INDEX TO VOLUME XV

GENERAL ALPHABETICAL INDEX

Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest).

A

Abbé, Paul O.	53
Abrasives. Aluminous abrasives from waste garnet. Davenport. (P.)	359
Abrasives. Finely Crystalline. Tone (P.)	359
Abrasives. Process of manufacture. Allen. (P.)	265
Acetic acid	480
Acetone	480
Acids, resisting iron apparatus. Design of Swindin	647
Adams, Roger C.	500
Alaska Gold Mines Co.	174
ALCOHOLS:	
— Cheap production. Breckler	380
— Ethyl alcohol from wood. Kressmann	78
— Industrial conference	480
— Large domestic order	562
Alkali metals. Fused electrolysis under pressure. McNitt. (P.)	654
Allen, A. P.	607
Allen, Arthur P.	710
Allen, Glenn L.	160
Allotropy of silver. Helderman. (S.)	599
ALLOYS:	
— Brass and copper. Clamer. (P.)	601
— Chromium. Driver. (P.)	102
— Copper-alkaline earth alloys. Temple. (P.)	102
— Manganin	574
— Nichrome castings. Henderson. (P.)	267
— To withstand internal air pressure. Sleeth	352
— Untarnishable iron alloy. Brearly. (P.)	655
Alumina inclusions in steel. Sauveur	149
ALUMINIUM:	
— Annealing of Seligman and Williams	244
— Castings and forgings. McKinney	351
— Composition for welding and soldering. Weatherford. (P.)	657
— Determination of	271
— Dust in gold and silver precipitation. Rose. (S.)	598
— Electrolysis of cryolite magnesium oxide mixture. Thompson	504
— Increase in Japanese industry	21
— Soldering. Litot. (P.)	657
Aluminum chloride. Effect of in formation of gasoline from oils. Egloff and Moore	340
Aluminous abrasives. Allen. (P.)	265
Alumite in British Columbia	52
American Alkali & Acid Co.	205
American Association for the Advancement of Science. Program of New York meeting	676
American Blower Co.	220
American Chemical Society.	
— New York section:	
— Report of meeting	561
— Revision of chemical statistics	505
New York meeting, Report	379
New York meeting. Ladies' committee program	230
Program of New York meeting	282
— Detroit section. Announcement of meetings	577
— Program of meeting with American Association for Advancement of Science	676
American Electrochemical Society:	
— New York meeting:	
— Program	124, 230,
— Report of	381
— Report of "Made in America" session	382
— Report of concluding sessions	482
— Program of Fall meeting	6
— Report of Committee on Public Relations on Nitrate Situation	172

— New York Section:	
— Meeting on chemistry of the gas industry	560
— Program of joint meeting with Illuminating Eng. Soc.	440
— Report of meeting with Illuminating Society on gas industry	621
— Program of meeting with American Association for Advancement of Science	676
American Electroplaters Society	53
American Foundrymen's Association. Exhibitors at Cleveland	292
American Institute of Chemical Engineers: — Cleveland meeting report	5
American Institute of Metals:	
— Program of Cleveland meeting	230
— Cleveland meeting. Announcement	292
— Cleveland meeting. Report	375
— New officers	500
American Institute of Mining Engineers— Arizona meeting	221
— Arizona meeting. Report	377
— Arizona meeting. Report	481
— Itinerary of Arizona tour	167
American Iron and Steel Institute. Announcement of St. Louis meeting	436
American Peat Society	408
American Physical Society. Program of meeting with American Association for Advancement of Science	676
American Products Co.	513
American Smelting & Refining Co., Hayden plant	170
American Society for Testing Materials— Report of Atlantic City meeting	10
American Society for Testing Materials— Report of Atlantic City Meeting	59
American Vanadium Co.	271
Amids, Manufacture. Ashcroft. (P.)	603
AMMONIA:	
— By-product coal ammonia as a domestic nitrate source. Riley	112
— By-product coal ammonia. Porter	470
— From coke ovens	38
— Ostwald process of oxidizing to nitric acid. Zeisberg	299
— Oxidation to nitric acid. Landis. (P.)	539
— Synthetic	220
— Synthesis of Zenghelis	318
Ammonium sulphate used in making carbon articles. Hincley. (P.)	359
ANALYSIS:	
— Cellulose in wood	53
— Determination of chromium in ferrochromium. MacFarland	279
— Determination of light oils in coal gas and description of method for separating the light oils from the absorbing oil. Duvall	626
— Determination of sulphuric anhydride. Pierce	353
— Nickel in iron ores. Covitz	582
— Oxygen, carbon monoxide and dioxide recorder	661
— Western Chemical Laboratories organized	710
— White bearing metals for copper and lead. Jackson	166
Anchor Mill	204
Anderson, W. P.	661
Angel, H. Reeve	499
Apparatus exhibit at Cambridge, Mass.	585
Arizona Copper Co. Flow sheet	484
Arizona. Metallurgical plants	167
Artificial fiber gas mantles. Knoedler	635

Asbestos, long fibred deposits in Arizona	537
Asphalt. Introduction of Colloids. Richardson	606
Asphalt. Research fellowship	500
Assay furnace. Bosworth type	660
Assaying. Cupellation losses in	219
Assaying. Distribution of silver between metallic lead and litharge-containing slags. Lathe	166
Association of Chemical Manufacturers	54
Automobile factories. Research needed. Ten Broeck	552
Auto tires. Use of rubber sponge inner tube. King	681
B	
Baekeland, L. H.	367
Bailey weir meter	267
Baker, David F.	219
Baker, Merrill G.	432
Ball mills. For regrounding. Kiliani	112
Ball mills. Hollinger Consolidated	372
Balke, C. W.	500
Baltimore Copper Smelting & Rolling Co.	220
Barite in Northern Ontario	544
Barium, Richards	27
Barrett Company	102
Barrows, Walter A., Jr.	102
Bartlett & Snow Co.	270
Barytes. Southern mining. Sandy Bottom Barytes Mines	616
Batteries. Active materials and electrolyte of the alkaline battery. Turnock	259
Batteries. Alkaline storage. Turnock	478
Bausch & Lomb Optical Co.	53
Bauxite. Increased production	87
Belgian Kiddies, Ltd.	669
Belts. Testing of conveyor belts. Robertson and Johnston. (S.)	262
Benzaldehyde and benzoic acid. Gibbs	380
Benzene (Benzol). See also Oils	
Benzol. Cracking of a gas oil. Egloff and Twomey	15
Benzol. From naphthalene derivatives. Egloff	125
Benzol. From coke ovens	39
Benzol. From thermal and pressure decomposition of pentanes and hexanes. Egloff	692
Beryllium. Richards	26
Bingham, Eugene C.	607
Bishop, F. L.	432
Bissel, G. M.	52
Bitumens. Introduction of colloids. Richardson	606
Bitumens. Outline for the study of	649
Blanchard, A. H.	432
Blast furnace. The Platan Process	653
Blasting with liquid oxygen in salt mines	161
Block Chemical Laboratories	312
Board of British Scientific Societies	372
Boiler tubes. Coarsening of. Howe	
BOOK REVIEWS:	
— American Fertilizer Handbook for 1916	220
— Brearley. Heat treatment of tool steel	545
— Bullens. Steel and its Heat Treatment	108
— Canadian Trade Index	660
— Charnock, G. F. Mechanical Technology	54
— Firth. Practical physical chemistry	711
— Flanders. Galvanizing and tinning	545
— Jobling, E. Catalysts and Its Industrial Applications	607
— Journal of the Institute of Metals. Edited by G. Shaw Scott	711
— Megraw. The Platan Process	545
— Le Bas. Molecular Volumes of Liquid Chemical Compounds	108

BOOK REVIEWS—Continued:

—Lewis. A system of physical chemistry	711
—Upton. Materials of Construction	36
—Williams. Niagara, Queen of Wonders	358
—Wilson. L. T. The corrosion of Iron	607
Borax. New fields in Chile	357
Boron. Copper castings containing boron. Gleason. (P.)	102
Bosworth Assay Furnace	28
Braden Copper Co. Roasting and acid plants. Wise. (S.)	660
Brashear, John A.	102
Brass. Annealing of arsenical brass. Thalheimer and Mathewson. (S.)	651
Brass. Effect of corrosion on the ductility and strength. Merica	321
Brass. Reclamation of brass as scrap. Taggart. (S.)	651
Brass. Seasoning, cracking and self-annealing. Arthur	651
Brass and copper. Clamer. (P.)	601
Brass Foundry	578
Brayton, C. C.	160
Brewing industry. Nowak	380
Brick. Methods for testing. Discussion of brick	601
Brick. Symposium on refractories	671
Bromine	203
Bromine. Equilibrium between bromine and potassium bromide solution. Jones and Hartmann	479
Brown Hoisting Mchry. Co.	220
Brown Hoisting Machinery Co. Rapid coil unloader	605
Brown Instrument	271
Browne, Wm. H., Jr.	432
Bruce, James L.	545
Bruer, Henry	607
Brunt, Frederick K.	710
Bully Hill. Electrolytic zinc	285
Bumgardner, J. W.	607
Burch, H. Kenyon	160
Bureau of Mines. New stations	165
—Proposed machine specifications	57
—Radium production	275
Burgess, J. A.	52
Burrell, George A.	499
Butte & Superior Copper Co.	174

C

Cadmium. Recovery from ores, flue dust, furnace products, etc. Stevens. (P.)	657
Calcium. Richards	27
Calcium carbide. New Norwegian factory	627
Calcium cyanamid. New Norwegian factory	627
California. New industries	285
California. New chemical industries	511
Calorizing as applied to power plant equipment	198
Calumet & Arizona Mining Co.	467
Calumet & Arizona. Flow sheet	482
Cameron, Frank K.	58
Canagire. Tannin and gualay rubber	482
Canby	668
Capillary Chemistry. Technical applications. Lewis	253
Carbolic acid. Manufacture in Germany. Raschig. (S.)	415
Carbon. Calcining furnace. Clymer. (P.)	103
Carbon articles. Use of ammonium sulphate. Hinckley. (P.)	352
Carbon dioxide recorder. Mono	549
Carnegie Institute of Technology. School of Applied Industries	219
Carrier Air Conditioning Co.	54
Captains of industry. Training of Hadfield	171
Castings, machinery, chilled, malleable and general. Johnson	683
Caustic soda. See also Sodium chloride (electrolysis)	487
Cells. Characteristics of small dry cells. Burgess	287
Cells. Electrolytic. Moore-Allen	288
Cellulose. In wood	53
Cement. Chemistry of Portland cement. Dickmann	41
Cement. Grading in the cement industry. Wiard	685
Cement. Properties of Rankin. (S.)	44
Cement. Tricalcium silicate in. Rankin. (S.)	213
Census of dyestuffs	710
Centrifugal pumps. Selection of. McEccle	679
Ceramic engineering. Building of University of Illinois	579
Cerium	30
Cerium and its compounds	357
Chain drive for aniline kettles	650
Chalburn, G. R.	432
Chemical Engineering. See Exposition	601
Chemical industries of French Indo-China	579
Chemical industries. Principles of organization. (P.)	612
Chemical prices. Reprints	712
Chemical terms. Inconsistency of some common terms. Hering	649
Chemist in public service	561
Child, Ernest	545

China Copper Co.	8
Chloridizing. Sulphide ores. Malm. (P.)	157
Chloridizing residue from leached copper concentrates. Addicks	628
Christensen, H. L.	607
Christensen, Nels C.	607
Chromium. Alloys. Driver. (P.)	103
—Effect of chromium in hardening steel. Edwards. (S.)	100
—Effect of foundry irons. Johnson	642
—Richards	29
Clarage Fan Co.	271
Clark, W. L.	68
Clays and their products. Schramm	576
COAL:	
—Bituminous output	152
—By-products as a source of fixed nitrogen. Porter	470
—Cost of. Smith and Lesher	631
—Grading in the coal industry. Wiard	685
—Iron production and coal reserves	434
—Powdered fuel vs. oil metal heating furnaces. Harrington	668
—Pneumatic powdered system	217
—Pulverized under stationary boilers	365
—Rapid unloader	605
—Cobalt. Electrolytic reduction of cobalt oxide. Guiterman. (P.)	601
Coho, H. B.	607
Cohoe, Wallace P.	219

COKE:

—British tar distillation industry. Coleman. (S.)	356
—By-products. Childs	38
—By-products as a source of fixed nitrogen. Porter	470
—By-product oven	222
—Increased by-product coking	56
—Increase in by-products	184
—Production in 1915	107
—Recuperator wall for ovens. Roberts	539
—Rotary pump for by-product service	658
Coke ovens. By-product. Determination of light oils from coal gas. Duval	626
Coke-oven accidents	10
Cole, Thomas F.	661
Colloids. Outline for study of bitumens	649
—Chemistry of Bancroft	379
—Emissions and suspensions with molten metals. Gillett. (S.)	540
—Industrial section of A. C. S.	381
—Introduction into bitumens. Richardson	606
—Metals, paints, rubber, plaster of paris	540
—Selective adsorption and differential diffusion. Alexander. (S.)	540
Colorado Central's old dumps being tested for process	507
Colorado Iron Works Co.	220
Colorado School of Mines. New president	281
—David	607
Coming meetings and events. Regular department. See index in front of this issue	
Commissioner of chemistry	223
Commonwealth Mining & Milling Co.	170

CONCENTRATION:

—Arizona meeting of A. I. M. E.	487
—Ball mill for regrinding Kiliani	112
—Dry process of Sutton, Steel & Steele	620
—Empire concentrating table	659
—Grading in the chemical and molten industries. Wiard	685
—Hartford Mining Co. remodeling 300-ton mill	561
—Increased output of mills	372
—Prince Consolidated mill	561
—Recovering values in mine dumps	507
—Selection of a method of ore treatment	297
—Screen efficiency	698
—Zinc in the Joplin district. Parmelee	319
Concrete. Specifications for concrete aggregates. Chapman. (S.)	213
Condenser. New thermometric	104
Conductivity. Its relation to microstructure	551
Conductivity versus chemical composition. Fink	464
Conductors. Analysis of tank resistance in electrolytic refining. Addicks	566
Conductors. Proper current densities. Hood	571
Congress. Time factors. Human affairs	4
Congress and technical affairs	164
Conklin, H. R.	203
Consolidated Arizona Smelting Co.	170
Construction news. Regular department beginning with Nov. 1 issue	
Converters in Arizona	335
Cooling towers	367

COPPER:

—Brass and copper alloys. Clamer. (P.)	601
—Castings containing boron. Gleason. (P.)	102
—Coatings on iron. Ruppel-Coles. (P.)	601
—Comparison of electrolytic and Lake copper. Mathewson and Thalheimer. (S.)	599
—Copper-alkaline earth alloys. Temple. (P.)	102

COPPER—Continued:

—Corrosion of tinned sheet copper. Merica. (S.)	415
—Dust losses at Copper Queen. Samuel. (S.)	155
—Flotation of oxidized ores. Ralston and Allen	154
—Flowing temperature of copper and copper-nickel mattes. Guess and Lathe	46
—Leaching:	
—Arizona meeting of A. I. M. E.	484
—Extraction process. Slater. (P.)	652
—Method of making leaching solution. Slater. (S.)	654
—Wet copper process. Greenway. (P.)	602
—Wet treatment of copper concentrates. Addicks	628
—Proper current densities. Hood	571
—Recovering from solutions. Schrater and Laughlin. (P.)	602
—Refining:	
—Analysis of tank resistance. Addicks	566
—Electrolytic apparatus. Greenaway. (P.)	158
—Electrolytic cell for copper solutions. Greenaway. (P.)	538
—Electrolytic cell construction. Greenaway. (P.)	634
—Metal tie-up. Addicks	305
—Sources of metal loss. Addicks	11
—Sources of metal loss. Liddell	279
—Refining process. King. (P.)	157
—Smelting:	
—Agglomeration of sulphides for pyritic smelting. Payne. (P.)	49
—Arizona meeting of A. I. M. E.	483
—Cost accounting in constructing and operating a copper smelter. Thum	96
—Features of new Arizona plants. McGregory	329
—Metallurgical plants in Arizona	170
—Notes on copper smelting at the United Verde Copper Co.	251
—Twinned crystals in electrolytic copper. Rawdon	406
Copper chief Mine	170
Copper Queen Consolidated. Flow sheet	482
Copper Queen Consolidated Mining Co.	169
Cork. Grading in the cork industry. Wiard	685
Corn Products Refining Co. Court orders	9
Cornell, Sidney	607
Cornish, E. J.	499
Corrosion:	
—Atmospheric of sheet iron. Richardson	450
—Effect on brass. Merica	321
—Testing the durability of pipe under corrosion. Speller	87
—Theory of the corrosion of steel. Aitchison	88
—Tinned sheet copper. Merica	415
Corwin, F. R.	710
Cost accounting. Construction and operation of a copper smelter. Thum	96
Cost system for manufacturers	271
Cotton gas mantles	638
Cottrell, F. G.	219
Cottrell dust-collecting system	331
Cottrell precipitation for phosphoric acid	380
Craddock, F. L.	106
Crushers. Symon's disc crushers	105
Crowley Co., John A.	220
Cunningham, Noel	219, 545
Cuntz, William C.	571
Current density charts	571
Cutler-Hammer Mfg. Co.	271
Cutting. Comparison of oxyhydrogen and oxy-acetylene. Schuck	218
Cyanamid. Process. Lidholm. (P.)	215
Cyanides. Electric furnace process. Linblad. (P.)	215
Daniels, Joseph	52
Degenhardt, W. R.	607
Delaney, C. R.	710
Deming, Horace G.	500
Denver Fire Clay Co.	271
Derick, C. G.	500
Desollars, T. C.	661
Detroit Chemists' meetings	577
Detroit Copper Mining Co.	170
Devine Co., J. P.	219
Digest of electrochemical U. S. patents	108, 162, 271
Distillation. Operation and costs of an eight-effect distilling plant. Leitch. (S.)	213
D'Olier Centrifugal Pump & Machinery Co.	107
Doerner, H. A.	106
Dolbear, Samuel H.	270
Douglas, James. Gift to United Engineering Library	622
Dow, H. W.	562
Dwight Oxygen Apparatus Co.	21

D

Drilling tools. Removing from oil and gas wells. Snelling. (P.)	658
Driver-Harris Wire Co. Castings.	159
DYESTUFFS:	
—British Dyes, Ltd., report	641
—British manufacture. (S.)	416
—Childs	40
—Coal-dye	40
—Future. Hesse	120
—Conference on American manufacture	440
—Dependent of Agriculture	291
—Design of factories for. Moses	29
—Government census available	710
—Industry developing in Japan	107
—New phase in. Hesse	120
—Under Congress	440
—Processes used in making intermediates. Ney and Van Marle	289
—Processes used in making intermediates. Ney and Van Marle	583
—Status of new tariff law	283
—Tariff. Hart	112
—The dyestuff	64
—Provisions of Revenue Bill, 1913	64

E

Economics. Swinburne and industry. Swinburne	687
Efficiency. Open fall conference.	687
Eimer & Amend. Electric structure.	571
Electric properties. American.	557
Electrical instruments. American.	574
Electrochemistry. Possibilities of Pacific Coast as compared with Sweden and Norway. Beckman.	18
Electrochemistry. Why people should interest themselves in it.	108
Electrochemical Industries of America. Fitz Gerald, Tone, Hooker, Edmands, Lidbury and Acheson.	115
Electrochemical industries and Western waterpowers. Langford.	166
Electrodes. Prevention of disintegration. Van Arsdele, (P.)	538
Electrolysis. High temperature heat development. Herge.	162
Electrolysis under pressure. McNitt, (P.)	654
Electrolytic refining. Metal tie-up. Adicks.	305
Electrotyping. Secor. Plaford.	162
—Apparatus. Hallock, (P.)	369
—Coating molds with graphite. Blake, (D.)	272
—Deposition ofopper. Blum, Holler, and Rawson	477
—Hangers for molds. Fertig, (D.)	162
—Holder, (D.)	162
—Mold, (D.)	162
Elements, Their essential attributes. Theod. W. Richards.	62
Elyria Enamelled Products Co.	270
—New laboratory	367
Emmons, N. H., 2nd.	542
Empire concentrating table.	659
Enamelled. Elyria Enamelled Products Co.	542
England. New courses in industrial chemistry	571
Erichsen. High firing for testing metal	270
Erisman, J. F., for testing metal	270
Evaporation. Simplex and multiplex evaporators for tannin extracts.	361
Evaporation. Simplex and multiplex evaporators. Simplex and multiplex effect evaporators.	361
Explosives. Hygroscopic properties of sodium, potassium, and ammonium nitrates, potassium chlorate and mercury fulminate. Taylor and Cope	140
Export. Common export trade.	53
Exposition. Second chemical:	
—Announcements.	160, 176, 221, 229,
—List of exhibitors.	283
—Opening exercises and list of exhibitors	418,

F

Paradise Society. Symposium on rec-	
tories	671
Fashinder, A. J.	432
Fash, R. H.	276
Federal Lead Co. New mill	276
Feldspar	627
of electrolytic potassium chlorate	627
Ferromanganese. Premelting device. (S.)	415
Ferromanganese. Production in electric	653
future	653
Ferromolybdenum. Manufacture. Fleck,	
(S.)	263
Fibrox. Examination of electrical proper-	
ties. Northrup	409
Filter. Portland	53
Filtration. Principles of.	198
Financial news. Regular department be-	
ginning with Nov. 1 issue	45
Fire brick. Effect of cooling on loads.	
Mellor and Moore, (S.)	45

Fire brick. Practical methods of testing. Nesbitt and Bell.....	20
Fire brick. Texture of. Mellor.....	67
Fire clays. Properties of plastic fire clays.....	140
Fire-resisting materials.....	141
FLOTATION:	
—Air flotation.....	27
—Bubbles. Clayton.....	27
—Calkine.....	46
—Callow cell.....	45
—Callow plant.....	39
—Cole-Bergman frothing classifier.....	39
—Devices for regulating the flow of oil.....	62
—Electric contents and flotation values of oils. Clayton.....	50
—Experiments in a Joplin tailing. Whitaker, Belchic, Neal and Van Velsor.....	11
—Explanation of the process. Taggart and Beach.....	25
—Flint-Towne machine.....	55
—History of the process at Inspiration, Gahl.....	39
—History of the process at Inspiration.....	45
—Interesting points in Miami suit decision. Schwarz.....	55
—Joplin zinc district. Parmelee.....	32
—K and K combine. Kohlstedt and Kraut. (P.).....	21
—Lead ores in Southeast Missouri.....	9
—Liquid jets. Ellis.....	42
—Miami suit.....	43
—Miami suit decision.....	44
—Minerals. Separation cells.....	39
—Minerals. Separation flotation machines.....	39
—Oxidized ores. Ralston and Allen.....	15
—Pine oil. Jones. (S.).....	53
—Report of Arizona meeting of A. I. E. C.....	48
—Tests at Santa Gertrudis. Ross. (S.).....	45
—The flotation of minerals. Anderson.....	8
FOUNDRY:	
—Chemical and physical properties of foundry irons. Johnson.....	68
—Theory. Gahl.....	37
—Vindicator test plant.....	37
—Zinc tailings at Joplin.....	37
Flue dust. Reduction of. Boggs. (P.).....	15
Flue dust treatment. Ryan. (P.).....	15
Fluorspar in 1915.....	10
Flynn, E. N.....	54
Foot, T.....	27
Formic acid. Electrolytic process of making. Vaygoun. (P.).....	57
Foundry. Brass. Barnes.....	57
Foundry. Chemical and physical properties of foundry irons. Johnson.....	58
Foundry. Chemical and physical properties of foundry irons. Johnson.....	62
Fox, A. M.....	68
Foxboro Co.....	27
French, E. B. Great Britain. Armstrong.....	57
Franklin medal. Presentation to Theodore W. Richards.....	6
Fraser, George W.....	10
French Indo-China. Chemical and mineral industry.....	60
Friday Copper Mining Company.....	56
Fuel economy in Great Britain. Armstrong. (S.).....	35
Fuel. In Russia.....	36
Fuel. Powdered coal versus oil in metal casting.....	56
Fuller Engineering Co. Lime plant.....	6
Fuller-Lehigh pulverizer mills.....	36
Furnace. Blasting lecture. Using coal, coke, oil or gas. Kenworthy.....	5
Furnace. Assay. Bosworth furnace.....	10
FURNACE: BLAST:	66
—Blast furnace performance.....	5
—Blast furnace products. Johnson.....	32
—Blast furnace tonnage. (P.).....	51
— Census of American industry.....	53
— Commercial considerations. Johnson.....	23
—Copper blast furnaces in Arizona.....	33
—McGregor.....	33
—Irregularities and their treatment. Johnson.....	6
—Irregularities and their treatment. Johnson.....	6
—Production of phosphorus. Gahl.....	1
—Rate of driving. Johnson.....	1
Furnace. Calcining carbon. Clymer. (P.).....	10
FURNACE, ELECTRIC:	
—General:	
—Electric furnace steels. Conference.....	43
—Gronwall-Dixon Anniversary.....	14
—Symposium on refractories.....	62
—Use in brass foundry. Barnes.....	5
—Various designs:	
—Carbon compounds. Imbuhl. (P.).....	21
—Leaves Electric steel.....	21
—Nitrogen fixation. Island. (P.).....	21

The Place Value of the Waterpowers of the Pacific Coast for Electrochemical Industries

In this issue we publish a very readable, enthusiastic and decidedly sensible paper by Mr. John Wood Beckman on electrochemical possibilities of the Pacific Coast states. This paper gives us a welcome opportunity to discuss in a few words the relative value of waterpowers in different localities. Waterpowers have been very much talked about recently. With what has been said about the urgent need of removing the unwise and directly foolish legal restrictions which hamper the development of American waterpowers at present in the most serious manner, we fully agree. But we are somewhat under the impression that the owners of waterpowers in different parts of the country, together with the commercial interests depending on them, have not always taken a scrupulously correct attitude toward each other. There have been some indications of jealousy or, shall we say, provincialism. It is perfectly natural that the owner of a waterpower thinks that his own waterpower is the most important. It certainly is for him. But we don't see the slightest justification for such jealousy as is natural between competitors in other lines. The reason is simply that as things are there can be very little competition between different waterpowers. The sphere of usefulness of a waterpower as potential producer of an electrochemical product can be accurately figured from the cost of power and of raw materials, operating cost, selling price and the very important item of freight charges from waterpower to market. Any waterpower has its own restricted market beyond which it cannot extend its usefulness economically, and it will be found that the market zones of the most important waterpowers overlap very little. All that is really needed in order to convince oneself of the truth of this statement is to tabulate the freight-rates from any one waterpower to the principal industrial centers of this country.

To give one concrete example which is rather extreme, we may refer once more to the present power famine in Niagara Falls. In order to find a remedy, it would be plain foolishness to think that the abundant and relatively cheap waterpowers of the Pacific Coast could be used as a substitute for Niagara power to supply the principal markets now supplied by the Niagara Falls electrochemical industries. The freight rates from the Pacific Coast to the manufacturing districts of the East and Middle West are prohibitive. Competition in this market between electrochemical products from Niagara power and from Pacific Coast power is therefore an economic impossibility. But has anyone ever seriously suggested this? Mr. Beckman's paper

is just one more proof that the Pacific Coast clearly understands the situation and looks out for its own market. But if there cannot be commercial competition why should there be not a real attitude of mutual helpfulness between the waterpower interests of the East and the West?

There is a very simple fundamental reason why freight rates are of such enormous importance in determining the selling zone of a waterpower as an electrochemical producer. It is a well-known fact that the usefulness of so many electrochemical products is due to the stored energy in them. In other words, that the sale of so many electrochemical products is a case of chemical power transmission. But chemical power transmission, unlike electrical power transmission, depends on ordinary transportation means—railroads, ships, etc.—and this fact makes freight rates all important in chemical power transmission. And this is even more so in this country than abroad. In our issue of March 15, 1916, in discussing the place value of waterpowers, we gave indisputable figures showing that while this country is easily the foremost industrial nation, in that it has succeeded in multiplying the natural working productiveness of its average citizen by industrial development, yet, on the other hand, this country is very much less industrially populated than England or Germany, and the cost of transportation between the different industrial centers among each other and between industrial centers and sources of raw materials and markets respectively is very much greater. This consideration explains why in the chemical industries certain things are possible in Germany which are impossible in this country. It also explains why Niagara's unique position among American waterpowers is, to a large extent, due to its connection to the Great Lakes, with 3600 miles of shore line and navigable to the very docks at Niagara. The least expensive sort of transportation is thus provided for Niagara products to markets representing nearly half the population of North America, while the least expensive supply of raw materials is provided in many cases by the same waterway, quite aside from the railroads running from Niagara in all directions.

Now, what are the possibilities of electrochemical industries on the Pacific Coast? Mr. Beckman discusses this very question in an interesting way by basing his discussion on certain analogies between the conditions of the Pacific Coast and those of Sweden and Norway. Of course, the Pacific Coast States themselves offer at the start a ready market for electrochemical products, and this market will grow, but it is not large enough, nor will it be large enough for a long time to come in order to absorb all the products that could be made with the immense waterpowers available and waiting for development. Mr. Beckman is right: the Pacific Coast will have to follow the lead of Sweden and Norway and look for export trade and learn "the art of handling tramp steamers." "We can reach from the Pacific Coast over one-half of the world's population by going west and south. Some of the markets are small, but they are bound to grow, and if we miss

the present opportunity somebody else will step in and collect the harvest which legitimately belongs to us."

Clearly, there are almost unlimited possibilities. But the amount of work that remains to be done to transform this vision into a reality is immense. Yet the pioneer spirit of the people of the Pacific Coast is just fitted for the task. When once the problem and the opportunities are realized; when, as Mr. Beckman puts it, an "electrochemical atmosphere" has been created, it may be safely left to the people of the Pacific Coast themselves to do the rest. The Pacific Coast has undoubtedly more potential wealth in its 11,000,000 hp. of waterpower, of which 93 per cent now goes to waste, than in all the gold that was ever mined or is still to be mined in those States. But an export trade must be created. The Golden Gate will then become the gate to a new and glorious future of the empire of the Pacific Coast.

Labor and Prosperity

The wages of men engaged in the production of the base metals are now quite generally based on the market price of metals, with a sliding scale that automatically adjusts wages to changes in the market. This arrangement has prevailed in the copper industry for several years, and has been adopted in some measure in the case of lead and zinc. Wages at the present time are accordingly much higher than before the war, due to the increased price of metals.

Assuming a fair and reasonable base wage and rate of increase, the idea is equitable and commends itself as a just means of insuring harmony and contentment. It appeals to the wage earner, particularly as long as prices rise and wages increase; but he takes a reverse situation with bad grace, even though it is still fair and equitable. Becoming accustomed to unusual prosperity, he seems to accept it as a standard condition and regards any unfavorable change as an encroachment on his established rights. He is not what is called a good loser, even though as a matter of fact he loses nothing except as the operator also loses. Labor may not be insincere in accepting sliding wage scales, but it shows moral incapacity when called upon to take reverses.

In the Joplin district wages for a certain class of labor were based at \$3.50 per day when zinc concentrate sold between \$50 and \$60 per ton, with an increase of 25 cents per day for each increment of \$10 in the average price of concentrate above the \$60 limit. Several times the operators have paid a 25-cent increase when the average price of concentrate for a month exceeded one of the \$10 limits by narrow margins of less than \$1. Recently when the average price of concentrate fell below one of the limits by only \$1.88, labor not only objected to the corresponding cut in wages, but demanded an increase of 25 cents per day over the current wage. Failing to get the increase, they threatened a strike.

Instances could be multiplied to show the unreasonableness of men after temporarily enjoying unusual advantages. It is a human trait and not a peculiar characteristic of prosperous labor, but it crops out in a most unfortunate way in the latter class and brings merited

condemnation. A little more reason, appreciation and sense of moral obligation would fortify labor's position in a marked degree.

A Scientific Tariff for Steel?

It is a fortunate thing for the iron and steel industry that both political parties are committed to the principle of a tariff commission. Both now carry the idea as a platform plank, and the party in power is enacting a tariff commission bill into law.

One may rejoine that the mere expectation that some sort of a tariff commission, with unknown personnel, is to be established, is narrow ground on which to congratulate the steel industry, but things must be considered in their relation. There could be nothing worse than the tariffs the country has had, or the methods by which they were constructed, or the utter abandon with which they have been modified. The condition has been so bad that practically any step would be a step toward better things, if not a step in precisely the right direction.

A tariff commission should be able to produce, eventually, a scientific tariff. It would be able to proceed upon known facts, as it gathered the facts, but that is only one feature. Hitherto the tariff has been revised simply as political need or political opportunity presented itself, the facts as to the course of trade, the volume of our imports or the volume of our exports of a given commodity having nothing to do with the determination of the party controlling the Congress to revise the tariff.

One of the things a tariff commission would necessarily do would be to study the working of the existing tariff, observing what material it let in and what material it kept out, then endeavoring to determine whether the flow of material, or lack of flow, was for the best interests of the country. A conclusion that the condition as to the specific commodity was not the best possible would result in a recommendation that the tariff should be modified. Thus developments in commerce, not developments in politics, would determine when and how the tariff should be modified. It is rather an elementary proposition that the tariff should be controlled by such influences, but there are various elementary principles that have thus far been ignored in the conduct of the Federal government.

That a tariff commission principle in the making of Schedule C of the tariff is particularly welcome at this time to the steel industry is due to the mental position of the steel industry itself. Hitherto the steel manufacturers have appeared at least to know what they wanted. As individuals they have expressed strong convictions in hearings of the Ways and Means Committee of the House and the Finance Committee of the Senate. It is true the convictions of the various individuals did not always harmonize, largely from insufficient rehearsal, one may surmise, but the fact remains that the steel men have claimed to know what they wanted. They even cited figures to prove it.

Now their position is different. There are no competitive conditions now. We are shipping steel to certain countries that formerly tried to get into our own

domestic market, and would gladly ship steel, if conditions permitted, to one country that has been the greatest steel exporter of all. American steel manufacturers do not know what competitive conditions will be like after the war. There are speculations of various sorts. Everything is uncertain. No one could determine now what rates would be best. What is needed is a system whereby the tariff rates will be quickly and sensitively responsive to conditions that develop when the war ends. To create and maintain such a tariff the commission seems the best that could be adopted. The establishment of the commission will be only the veriest beginning. A tremendous responsibility will rest upon it, and in its conduct there should not be too much of the "celerity contempered with cunctation" referred to by a recent governor of Pennsylvania.

War Prices, Smelting Schedules and Profits

We have become so accustomed to linking the war price of metals with high profits to producers that it is an anomaly to find a company that is not as prosperous under present conditions as it was a year ago with a normal metal market. One such case has come to our notice, and probably it could be duplicated. The company ships a concentrate containing lead, copper and silver, to the local plant of a large lead-smelting concern. The schedule of rates and charges is the one generally in force in a district of comparatively small mines and companies.

Comparing profit from shipments to-day and a year ago, a strange situation is revealed. On a recent shipment made when lead, silver and copper were quoted at abnormally high prices, 48 per cent of the gross market value of metals in concentrates was absorbed by the smelter, leaving the shipper 52 per cent. A year previous, when metals were at a much lower price, concentrate of about the same grade was shipped, but only 39 per cent of the gross market value of the metals was absorbed by the smelter, leaving the shipper 61 per cent. When the net return under the high price of metals was figured back to profit per ton of crude ore, the slight increase over a year ago was found insufficient to offset the greater cost per ton of labor, powder and other supplies.

In another case the shipper received only 49 per cent of the gross market value of the metals, figuring silver at 64 cents, lead at 7 and copper at 27, or \$22.67 per ton. Calculating the return from the same concentrate under normal prices for metals, say silver at 53 cents, lead at 4 and copper at 14, the return to the shipper would have been \$16.85. In other words, with silver advanced 11 cents per ounce, and lead and copper all but doubled in market value, the net increase to the shipper was but \$5.82 cents per ton, or only about one-third more than he would have received at normal prices.

Two elements combine to produce this condition. The first is the obvious increase in the cost of operation. The second is the nature of the smelting schedule, which, while it is designed to encourage production when metal prices are low, enables the smelter to reap most of the benefit when they are high.

The Time Factor and Catalysis in Human Affairs

To the Editor of Metallurgical & Chemical Engineering

Sir: Things are not going right in public affairs. Some features seem to be getting into the way of betterment, although the process appears almost imperceptible to the naked eye. For instance, in New York City there are thousands of children of school age that are unable to secure school accommodations. And yet, under the Wirt system, with some additional equipment, every child in New York could enjoy full school time and there would be facilities to spare. On the Board of Education there are earnest and sincere men of constructive mind and disposition. But the whole thing is tangled up with politics, the mayor lacks power, vested rights in the form of somebody's prospective profits stand in the way—and the children are growing up on the streets. There is money enough, there are schools enough, there is, indeed, everything in plenty except intelligence and character in a small part of the Board of Education—and time. A part of the board plays politics and holds back progress, but the board, as a whole, is intelligent enough. Trouble is, the city is too big, the board is too big and the whole system is too big to do anything at once. It looks as though New York would have a good public school system in time, but many children of the present generation are growing up just where they should not grow up.

A recent issue of "Commerce and Finance"—a very readable paper withal—tells under "Grafting on the State" the findings of the Brooklyn Young Men's Republican Club in regard to the expenditures of the representatives of the State of New York in connection with the Panama-Pacific Exposition. It was a little matter of \$700,000. First there was a handsome temporary building put up that housed no exhibits. Dishes, silverware and glasses from Tiffany's cost \$5168.25. Various banquets given there cost over \$2000 each. Three New York State commissioners took trips to Europe "to get into touch with exhibitors" to no real purpose whatever. Any number of State officials and commissioners having nothing to do with the exposition took trips to California and back with their entire families—and charged everything to the pork barrel. A gentleman of the commission spent some time at Hotel Knickerbocker in New York and his expense account for three days was: Room, \$21; restaurant, \$63.03. It all came out of taxes.

For the week previous his expenditures were more modest, being as follows:

Feb. 14:	Breakfast..	\$4.85	Lunch..	\$4.90	Dinner..	\$7.85
" 15:	"	4.65	"	4.75	"	7.60
" 16:	"	4.10	"	5.25	"	7.45
" 17:	"	4.85	"	4.80	"	9.10
" 18:	"	4.20	"	3.90	"	7.80
" 19:	"	3.85	"	4.10	"	7.80
" 20:	"	4.10	"	...	"	7.90

all of which was charged up.

A dinner to the Hon. Seth Low cost \$2402—at least that sum was charged to the State of New York for it, and we know that Mr. Low is the last man on earth to approve of that sort of thing. We doubt if he had knowledge that it was not a subscription dinner. For Governor Whitman and his suite a special train was chartered. The cost to the State was over \$1000 a day, for twenty-four days.

Every member of the party ate over \$25 worth of

food per day—if the figures are correct. That is what the State of New York paid for. Now there are many State commissions that do nothing but junket on money gathered from taxes, but there are others, permanent ones, that are so well manned, that do such good work, and at such cost of time to the really able men who constitute them, that the waste of their unscrupulous colleagues is neutralized. In time such scandalous proceedings as the debauch of the Exposition Commission will cease. Trouble is, New York is a big State, and it takes time to get over these things. Time and then something else.

Some time ago reference was made in "Metallurgical & Chemical Engineering" to the present Congress, and it was noted that during the first seven days of its session there were many bills introduced of which 5 per cent were for the public welfare and 95 per cent were designed chiefly to give public money to private persons. The history of Congress since then has been very little better. We want so much from it in the way of progressive legislation that it would seem to be the part of wisdom to placate the gentlemen with kind words. We do not hesitate to say that there are some men there who deserve all praise, and who hold aloft ideals of patriotism and integrity in a way to do us all proud. To them we accord all praise. But Congress is not wholly made up of that sort. A large number of its members are loud-mouthed shysters and pettifoggers who are too blind to see, too stupid to think, too selfish to feel and totally unworthy to be intrusted with public affairs. The type of men that we, as citizens, have allowed to creep into elective offices without a protest is a shame to all of us. And unless an enlightened public conscience arises in its might and drives the men of subnormal character out of elective offices, there will be no better chance for decent business in this country than there is in Mexico. This is the part that is up to us as electors. Congress, as we have said before, is US, the people. It reflects *our* intelligence. If we improve in intelligence and character, so will Congress. If we drop off, Congress will increase in noise and decrease in mind. But whatever happens, owing to the great mass of people and the number of their representatives, the process is bound to be slow; very, very slow.

The time factor, however, is not stable. It is subject to remarkable acceleration by the catalytic action of public opinion. As soon as the public learns, for instance, that many millions of dollars of Uncle Sam's money is to be spent by State officials on, let us say, militia, and that without any adequate check upon the way in which it is to be expended, the State officials will have to produce the goods—will deliver soldiers instead of politicians with epaulettes and men who play at drill once a month.

If the income tax, for instance, touched small incomes, no matter how slightly, the chances are that public opinion would be aroused and the time factor in the elimination of graft would be reduced in an amazing measure. Catalysis in human affairs is a very interesting subject.

The National Fertilizer Association will hold its twenty-third annual convention, together with the Southern Fertilizer Association at the Homestead, Hot Springs, Va., July 10 to 14.

Cleveland Meeting of American Institute of Chemical Engineers

The eighth semi-annual meeting of the American Institute of Chemical Engineers, held in Cleveland, Ohio, from June 14 to 17, 1916, proved very enjoyable. It was probably the best attended meeting the Institute has held so far, while the local committees had provided an excellent program of entertainments.

WEDNESDAY MORNING SESSION

The opening session was held in the Hotel Statler on Wednesday morning, June 15. The attendance at this session varied between 50 and 75. As President Rosengarten was unable to attend on account of a serious automobile accident, the meeting was called to order by Professor J. H. JAMES.

In his address of welcome Mr. RALPH L. FULLER, president of the Chamber of Commerce and vice-president of the Harshaw, Fuller & Goodwin Co., called attention to the large number and the variety of chemical industries in Cleveland and vicinity. He emphasized that these industries were in sore need of a protective tariff in view of the conditions likely to be met with after the war. He suggested the advisability of a concerted effort by the American Institute of Chemical Engineers and similar organizations toward securing adequate and effective protection for the chemical industries which have been started or largely expanded during the last few years to meet present conditions.

Secretary JOHN C. OLSEN of the Institute replied to Mr. Fuller and expressed his appreciation of the fact that the Institute had been welcomed to Cleveland by a chemical engineer and manufacturer equally familiar with technical and business problems. He thought the suggestion of the Institute taking active steps to endeavor to secure suitable tariff legislation was feasible.

The report of the treasurer, Dr. F. W. Frerichs of St. Louis, Mo., showed a very substantial balance on hand. The secretary reported that 27 applications for membership had been received since the winter meeting and nine new members had been elected.

The Committee on Meetings reported that invitations for the next winter meeting had been received from St. Louis and New York. New York appeared to be favored by those present.

A progress report was presented by the Committee on Patents of which Dr. Baekeland is chairman.

Two technical papers were then read and discussed. Professor JOSEPH W. RICHARDS presented a paper on "the production of the rarer metals." This paper, which was of especial interest on account of various suggestions as to the lines along which improvements in the manufacture of the rarer metals are possible, is printed in full elsewhere in this issue.

In a paper by Professor E. E. WARE and R. E. CHRISTMAN on "the effect of storage on mixed paints" it was shown that deterioration in mixed paints is frequently due to the presence of zinc oxide.

WEDNESDAY AFTERNOON EXCURSIONS

On Wednesday afternoon the Central Furnaces and the Semet-Solvay by-product coke-oven plant of the Cleveland Furnace Company were visited. The melting of the steel in open-hearth furnaces (of which there are 100 of 50-ton capacity), heating in soaking pits and passage through the rolling mills were seen. In order to obtain a uniform product, two mixers of 400 tons capacity are used. The Garrett continuous rod mill was inspected with interest, also a Bessemer converter in operation.

At the Semet-Solvay plant a bank of 100 ovens of 800 to 1000 tons daily capacity was inspected. Ammonia and light oils are recovered from the gas which is worked with petroleum to recover the light oils.

WEDNESDAY EVENING SESSION

The evening session was held at the University Club, Professor J. H. James presiding.

The first paper presented dealt with "nitric acid sophistication," the author being Professor JAMES R. WITHROW. The examination of a shipment of nitric acid from which crystals of sodium nitrate had been deposited was the occasion for a study of the solubility of sodium nitrate in nitric acid of various strengths. It was found that as much as 6 per cent of this salt could be dissolved producing a considerable increase in specific gravity. The presence of considerable amounts of calcium chloride in muriatic acid was reported during the discussion.

A paper by Mr. HERMAN STABLER of the U. S. Geological Survey, on "water powers of the Western United States," gave a list of water powers which have been developed in the Western states, aggregating 1,396,000 hp. Most of this power is used for electric lighting, electric traction and general municipal purposes, but not for electrochemical industries. A list of possible developments aggregating 5,708,000 hp. was given.

In the discussion of this paper it was brought out, especially by Mr. F. A. LIBBURY, that on account of cost of transportation electrochemical industries cannot be located west of the Mississippi to supply the market of the East and Middle West. On account of the limited amount of power available at Niagara Falls electrochemical industries cannot expand there and are being relocated in Canada, France or Norway.

After the reading of the papers the members were entertained as guests of the local committee at a highly pleasant smoker with a musical program.

THURSDAY EXCURSION

Thursday morning the members were taken by automobile to the ore docks of the Pennsylvania R. R. Much interest was shown in three Hulett unloaders which were transferring the ore from an ore boat to railroad cars. The capacity of the buckets is 17 tons. The best record for unloading an 11,800-ton boat is 3 hours and 35 minutes, including weighing and loading on cars; the usual time is 4 hours.

The Cleveland filtration plant was then visited. This plant is built for the treatment of 85 million gallons of water. The purification consists of precipitation and clarification with ferrous sulphate, sedimentation, rapid sand filtration and chlorination. Mechanical sand filters are installed.

The plant of the National Carbon Co. was then visited. Dr. W. C. Moore guided. At this plant the manufacture of electric arc carbons was inspected, special interest being shown in the carbons used for the flaming arc lamps. Interest was also shown in the brushes for electric dynamos. Fifty grades are being manufactured. The methods in use for testing these brushes were shown. The manufacture of dry cells and methods of testing were also shown.

Luncheon was served at the Case School of Applied Science, an address of welcome being made by Prof. F. A. MABERY, who gave a short account of the formation and development of the school. Secretary Olsen responded, stating that the chemical engineers recognized that the varied chemical industries of Cleveland owed much of their prosperity and existence to Case School, which had furnished the technical men who carried on the industries.

LECTURE ON SOUND

After luncheon the chemical engineers were entertained and instructed by an admirable lecture by Prof. D. C. MILLER on "sound." Special interest was shown in the phonodyke, an instrument devised and built by Dr. Miller by which the curve of any sound may be thrown on the screen. The audience was delighted to watch the ever-varying curves produced by the music of a phonograph as well as those produced by the cheers and encores which greeted Prof. Miller's wonderful achievement. The sound waves were magnified 40,000 times. The mirror of the phonodyke weighs 2 milligrams and can vibrate 12,000 times per second.

The physical and chemical laboratories were then inspected with great interest.

DINNER

The subscription dinner was held in the evening in the beautifully decorated library of Hotel Statler. About 65 were present. Prof. A. W. SMITH acted as toastmaster, introducing first Dr. WILLIAM C. MOORE, chairman of the local section of the American Chemical Society, who spoke of the work of the local chemists. Mr. F. H. LEE, of the Grasselli Chemical Co., and chairman of the local committee of arrangements for the meeting, spoke of the efforts of his committee to make the visitors welcome. Dr. T. B. WAGNER was introduced as the only ex-president of the Institute present at the meeting and amused the party by telling of his efforts to be relieved of the duties of being ex-president. Mr. JOHN C. HEBBEN related his experience in building the plant of the Federal Dyestuff and Chemical Co. at Kingsport, Tenn., which is now in successful operation. Prof. A. H. WHITE told many amusing stories and spoke very interestingly on progress in chemical engineering education at the University of Michigan. Secretary J. C. OLSEN, in a toast to the "Institute," emphasized the substantial growth of the Institute and its bright prospects for the future.

FRIDAY EXCURSIONS

On Friday the members were taken by automobile to the National Lamp Works of the General Electric Co. at Nela Park where incandescent lamp bulbs are blown. The glass furnaces were inspected and the clean and orderly condition of the entire plant was greatly admired. The time of blowing a bulb was found to be 20 seconds. The Smith gas producer used in the plant was then inspected.

The cutting and decorating of the globes was then shown as well as the method of testing the bulbs not only for life of the bulb, but also for candle power. Interest was shown in the photometric room, which is one of the best equipped in the world. Tests are made of the light emitted by the lamp at any angle with an accuracy of one-tenth of one per cent.

The research laboratories were then visited, where methods of producing artificial day light were shown.

FRIDAY AFTERNOON SESSION

The company then proceeded by automobile to the Country Club, where an elaborate lunch had been arranged for by the Grasselli Chemical Company in honor of the visiting chemical engineers.

After luncheon an illustrated lecture was given by Prof. EDWARD BARTOW on the experiments on purification of sewage by activated sludge which have been carried out at the University of Illinois. Analyses of the gases evolved show considerable oxidation of the carbon in the sewage.

The Cleveland experiment sewage disposal plant was then visited. Mr. R. Winslow Pratt acted as guide.

A one million-gallon unit for the purification of sewage by means of activated sludge is in operation. The sewage is subjected to the air for about one hour, $\frac{3}{4}$ cu. ft. being used per gallon of sewage. The raw sewage contains about 98 parts of iron per million gallons. This iron is precipitated, giving the sludge a brown appearance. The sludge contains about 3.5 per cent nitrogen, 2 per cent phosphorus pentoxide, 0.23 per cent K_2O and 7 per cent fat.

FRIDAY EVENING SESSION

On Friday evening a joint meeting with the Cleveland Section of the American Chemical Society was held at the Hotel Statler, Dr. T. B. WAGNER presiding. A paper on "acid-resisting alloys" by W. C. CORNELL was read and discussed at considerable length, Mr. F. A. LIDBURY spoke on "the electrochemical industries of the United States," and the report of the Committee of the New York Section of the American Chemical Society on Co-operation between Universities and Industries was read.

SATURDAY EXCURSION

On Saturday the members proceeded by a special trolley car to Akron, Ohio, where the works of the Goodrich Rubber Company were visited. The manufacture of automobile tires was first shown, including both cloth and the silvertown cord tires. The manufacture of waterproof clothing, conveyor belts and hood rubber articles was shown. Especial interest was taken in the very large jars for submarine batteries.

A complimentary luncheon was then served by the Goodrich Company at the Country Club. On return by trolley the meeting adjourned. The attendance, which was the largest in the history of the Institute, was unusually great in the Saturday excursion.

A fine program for the ladies was also carried through very successfully. It included an automobile trip to Lorain and Elyria, with complimentary supper at the Country Club at Elyria, also an automobile trip through the beautiful Cleveland park system and a theater party.

Program of the Fall Meeting of American Electrochemical Society

The fall meeting of the American Electrochemical Society will be held in New York City on Sept. 28, 29 and 30, 1916, that is, on Thursday, Friday and Saturday of the week of the Second National Exposition of Chemical Industries. The outline of the program is as follows:

Wednesday, Sept. 27, evening: General Reception, with registration, at the Chemical Exposition, Grand Central Palace.

Thursday, Sept. 28, forenoon: Reading and Discussion of Papers. General subject: "Made in America." Luncheon.

Afternoon: Visiting the Exposition.

Evening: *Complimentary Smoker.* An invitation will be extended to the members of the American Chemical Society and other visiting chemists and engineers.

Friday, Sept. 29, forenoon: Reading and Discussion of Papers.

Luncheon.

Afternoon: Visiting the Exposition.

Evening: *Subscription Dinner-Dance.*

Saturday, Sept. 30, forenoon: Reading and Discussion of Papers; possibly an excursion.

Luncheon.

Afternoon: Visiting the Exposition.

Mr. F. A. J. FitzGerald is president and Dr. Joseph W. Richards, Lehigh University, South Bethlehem, Pa., is secretary of the American Electrochemical Society.

The arrangements for the New York meeting are in the hands of the New York Section of which Dr. Colin G. Fink is chairman and Mr. J. Malcolm Muir, 239 West Thirty-ninth Street, New York, is secretary.

The Western Metallurgical Field New Mill of the Federal Lead Company

The Federal Lead Co. is one of the largest operators in the lead district of southeast Missouri. In addition to the 5000-ton mill which it is already operating it now has under construction a new 2500-ton mill which will be in commission this fall. Preparations for this plant were begun on Aug. 4, 1915, and from present indications it will be in operation within a year of that date, which will be a creditable performance considering that virgin land had to be cleared, wagon roads and railroads built, temporary structures erected for the accommodation of workmen, and an entirely new community established.

The site is on a hillside, at the bottom of which is the shaft and coarse-crushing department. From the shaft the ore will be conveyed by belt to the gyratories and thence to Symons disc crushers. The product of the latter will discharge onto an inclined belt conveyor leading to the mill bins, where it will be distributed by cross-conveyor.

The foundation and substructure of the mill building, including ore bins and jig and table floors, are of reinforced concrete, and the superstructure is of steel, giving a plant that will be light, clean and conveniently arranged.

Profiting by past experience at the old mill and by the general changes that have taken place in concentration throughout the district, the company will have an extremely simple flow-sheet for the new mill. The crushed ore will be separated into sizes suitable for jigging, tabling and flotation, and will be treated on six Hancock jigs, forty tables and a flotation plant consisting of Door thickeners, Janney agitation machines and air cells.

A Problem in Lead-Zinc Separation

A troublesome product made in varying quantity at the lead concentrating mills of southeast Missouri is a middling of zinc, lead and iron sulphides. The material makes its first appearance in the jigs, but is reground and retreated until finally it is discarded from the concentrating tables. At some of the mills it is separated and stored, awaiting future disposal; at others it is reground and redressed to yield a low-grade lead concentrate which is shipped to smelters. Mechanical methods have failed to make a satisfactory separation of the constituents of this material, and considerable experimenting has been done to determine an economical method of treatment. Roasting and magnetic separation do not give satisfactory results, nor does any system of grinding and concentration, either wet or dry. The minerals are so intimately associated that some hydrometallurgical scheme seems necessary for their separation and recovery, and further work is being done along this line in the hope of solving the problem. Possibly roasting and leaching would effect a separation of the two valuable metals, leaving lead in the residue and giving a solution of zinc for electrolysis.

Flotation of Zinc Tailings at Joplin

The first individual flotation plant to operate on a commercial scale in the Joplin zinc district is that of the Mining & Flotation Company of Denver, under the direction of S. P. Warren who designed and

erected the mill. The material treated is taken from an old tailing dump on a lease of the Granby company at Chitwood, and contains about one per cent of blende and a small quantity of galena. It is brought to the mill by teams and scrapers, dumped over a grizzly and elevated with water to a trommel screen of 1-mm. mesh. The oversize is discarded. The undersize is deslimed by an inclined screw conveyor giving a coarse sand discharge and slime overflow. The sand is classified and treated on four tables, while the slime is thickened in a V-box and pumped to the 6-cell flotation machine. An oil mixture, containing mainly pine oil, is added at the first cell and the mixture flows successively through the six cells of the machine. The tailing is discarded, but the frothy concentrate is dressed on a concentrating table in order to raise the grade in zinc. The table tailing and middling is returned to the flotation machine. About fifty per cent of the total mill production is made by flotation and the balance on the four tables. The mill is treating 80 tons of material in 10 hours and producing 1600 pounds of 50 per cent zinc concentrate.

The Tungsten Situation in Colorado

Following the sharp reaction in tungsten prices which demoralized the market several weeks ago, there has been a gradual recovery, and the large producers are continuing operations as usual. The Primos Mining & Milling Co. has remodeled the crushing department of its large plant at Primos, abandoning the stamps which have been criticized on account of their production of slime. The same company is continuing the construction of a new mill at Crescent in Boulder county, and the Rare Metals Extraction Co., composed of Cripple Creek operators, also is building a new custom mill at Rollinsville, which is expected to be in operation by July 1.

In an effort to make themselves independent of an uncertain market for tungsten concentrates, some operators are investigating the possibilities of making ferro-tungsten. Thus far the proposal seems feasible, for power is at hand from the hydroelectric plant of the Colorado Power Co., and specially high-grade concentrates could be produced without difficulty. Current specifications for ferro-tungsten, which the local producers would have to meet, demand a specially low content in carbon and phosphorus. Other deleterious substances are sulphur and manganese. The following limits are imposed: Tungsten, not less than 70 per cent; carbon, not more than 0.6 per cent; phosphorus and sulphur, each not more than 0.05 per cent; manganese, not more than 1.0 per cent. In case the concentrates produced are not rich enough to yield a ferro-tungsten containing 70 per cent tungsten, it may be necessary to produce some tungstic acid to add to the charge. In addition to the proposal to make ferro-tungsten, there is also a possibility that tungsten metal in powdered form may be made from tungstic acid. The latter article is now produced in the district. The recent flurry in the market has impressed on operators the necessity of greater independence, and it is likely that they will not stop at making concentrates but will extend their operations to include a more finished product.

Resolutions Favoring Nitrogen-Fixation Plant

At a recent meeting of engineering and scientific societies held in Denver, attention was directed to the importance of constructing in this country suitable manufacturing plants for the fixation of atmospheric nitrogen. A committee was appointed consisting of representatives of the national engineering

institutes, to draft resolutions for endorsement by the Colorado sections of those bodies, for presentation to Congress. These resolutions set forth the economic and industrial importance of nitrogen and its compounds, and urge upon Congress the necessity of action that will aid in the development of nitrogen-fixation plants, both by private enterprise and by the federal government. Congress is asked to appropriate \$100,000,000 for the purpose. The resolutions have been submitted to the members of the Colorado bodies, and have been endorsed by several of them.

Company Reports

The 1915 annual reports of the five important porphyry copper producers, **Utah, Ray Consolidated, Nevada Consolidated, Chino and Miami**, contain unusually interesting and important information, showing marked increase in efficiency of operation and decrease in cost of production, despite the fact that operations were not conducted at full capacity during the first part of the year. The following tabulation contains essential data on milling.

CONDENSED DATA FROM ANNUAL REPORTS, 1915, OF PORPHYRY COPPER COMPANIES

	Utah Copper	Ray Cons.	Nevada Cons.	Chino	Miami
Ore reserves, tons	390,000,000	71,911,475	50,525,289	90,000,000	35,140,000
Ore reserves, % Cu	1.447	2.235	1.652	1.75	1.82
Ore milled, tons	8,494,360	2,848,969	3,061,520	2,379,800	1,348,122
Ore milled, % Cu	1.434	1.673	1.540	2.155	2.17
Ratio of concentration			7.18	15.02	
Concentrates produced, % Cu	19.17	19.29	7.77	21.55	41.91
Percentage recovery	64.13	64.11	70.12	68.59	75.17
Copper produced, lb.	156,207,376	62,540,196	62,726,651	68,293,893	41,822,059
Cost of milling, ¢ per ton	34.02	50.86		54.19	57.94
Cost of copper, ¢ per lb.	(7.566)	(9.476)	(8.676)	(7.126)	
	16.61c	(9.423c)	(8.23c)	(6.75c)	6.05d

^aIncludes 1,425,682 lb. ore shipped direct to smelter.

^bAverage net cost after making allowances for smelter deductions and crediting gold and silver values, etc.

^cAverage net cost after crediting miscellaneous income.

^dCost of refined copper in concentrates on cars at Miami.

In addition to the foregoing, the following items pertaining to the different companies may be given. The **Utah Copper Company** milled 1,252,295 tons more ore than in 1914, and for the last six months of 1915 the daily capacity was 26,537 tons, or 33 per cent above normal capacity. Investigative work was done looking toward the treatment of the oxidized capping which has been and is being removed from the sulphide ore bodies. A leaching plant has been authorized, with an initial capacity of from 2000 to 3000 tons per day, and arrangements have been made to participate equally with the Garfield Smelting Co. in financing the construction and operation of a sulphuric acid plant near the latter company's smelting works.

At the smelting plant of **Nevada Consolidated**, improvements were made in the roasting department, whereby the tonnage of concentrates calcined per furnace day averaged 86 tons, as against 76 in 1914. In the reverberatory department a considerable reduction in cost per ton of material treated was obtained. The cost of converting was the lowest ever obtained since the converters were blown in, being \$9.76 per ton of blister copper. The grade of matte was considerably lower than during any other year, being 27.2 per cent copper.

Increase in tonnage treated was obtained by the **Chino** company during the last eight months of 1915, when an average of 1573 tons per section-per day was treated.

The **Miami** company showed a marked increase in percentage recovery, from 69.93 per cent in 1914 to 75.17 per cent in 1915. The grade of concentrate also

was increased from 39.31 per cent copper to 41.91 per cent. An experimental plant for the treatment of oxidized copper ore may be started in the near future. Laboratory results on this work have been encouraging.

The Iron and Steel Market

The significant fact in the dullness of the steel market is that it has developed no weakness. On the contrary, the situation is clearly a strong one, and this is a fact that could not be well brought out in an active and steady market. There is absolutely no disposition on the part of mills to cut base prices of finished steel for forward deliveries. It is true that premiums for prompt and early deliveries have continued to dwindle, until now they are almost negligible, except in the case of plates.

Strictly new buying of steel products is very light, and there is also a decrease in the volume of specifications filed against current contracts. There will be a further decrease in the total volume after July 1, as a number of relatively low-priced contracts expire by limitation with the June quarter.

Export demand continues heavy. Since the early part of April the export demand has continuously been heavier than at any previous time since the war started, but there is this change, that a month or two ago by far the major part of the export demand came from the allied belligerents, whereas of late the demand from neutral countries has been much more pronounced. The demand from neutrals is in part a reflection of lower ocean freights and in part a reflection of the complete exhaustion of their steel. The opening of the war found the countries that are far removed from sources of supply with large stocks of steel, while the actual consumption was greatly reduced. In the early months of the war there were many who predicted that the real demands of neutral countries would not find expression in actual buying until more than a year had elapsed. In some quarters the opinion is expressed that the volume, in tonnage, of export business is greater than that of domestic.

The dull domestic market is generally expected to continue through August. Then there should be a resolution of forces. While the large mills are filled with business quite comfortably through the year, and to an extent into the new year, many of the smaller mills are filled only for two or three months. A continued dull market would necessitate their seeking additional business within two or three months, while on the other hand the development of an amount of fresh demand, quite moderate in proportion to the total capacity of the country, would probably find insufficient mill capacity open to meet it.

In prognostications for the future account must be taken of the fact that even at this time a considerable proportion of the steel being shipped is invoiced at relatively low prices, being in fulfillment of old orders. The present rate of consumption is not necessarily an index to the rate that would obtain were all consumers, down to the ultimate consumer, forced to pay the present mill prices for finished steel.

Pig Iron

An unprecedented situation has developed in the Southern iron market. When the market was low last year a great deal of iron was bought speculatively, most of it in warrants. The typical speculative holder of pig iron warrants refuses to sell when the market is advancing, i.e., when consumers are buying pig iron, and insists upon selling when the market has stopped

advancing, i.e., when consumers will not buy. As a rule he thinks the pig iron market should absorb pig iron as the stock market absorbs stocks, but sometimes it will not do so. Ordinarily pig iron warrants can be disposed of, even in a dull market, at a slight concession from the furnace price, but in the past fortnight, as Southern iron offered by furnaces was declining slightly, to \$14.50, Birmingham, warrants were sold at \$13.50, and even in a few instances at \$13. The effect of these transactions has been to block the regular business in Southern iron and to affect sentimentally the position of buyers of Northern iron. We quote: No. 2 foundry iron, delivered Philadelphia, \$19.75 to \$20.25; f. o. b. furnace, Buffalo, \$18.50 to \$19; delivered Cleveland, \$19.30 to \$19.80; f. o. b. furnace, Chicago, \$19; f. o. b. Birmingham, \$14.50 to \$15 for furnace iron, warrant iron unquotable; f. o. b. valley furnaces, 95c higher delivered Pittsburgh; Bessemer, \$21; basic, \$18.25; foundry, \$18.25 to \$18.50; malleable, \$18.25; forge, \$18 to \$18.25.

Steel

The billet and sheet bar market is a trifle easier. Soft steel to be made to specifications as to size and analysis is not over \$42 for Bessemer and \$45 for open-hearth. Odd lots arising in the course of steel mill operations usually bring \$2 to \$3 a ton less, while nondescript material, chiefly second discards and rejections arising in the filling of shell steel orders, go at widely varying prices, according to whether they suit the requirements of a purchaser or are acceptable only because they are cheap.

Non-Ferrous Metal Market

Monday, June 26.—Dullness has characterized the market for most of the metals during the last two weeks, and a general decline has taken place. This is especially true of copper, lead, spelter and antimony. The consumption of tin is very good, and although it has been declining, it shows signs of reacting and developing strength again.

Copper.—The copper market has been dull and weak and spot electrolytic has dropped about 1 cent per pound to 26.75 cents. Producers are not cutting their prices as they have no substantial amount of copper for sale for delivery earlier than the last of the year. The labor situation is largely responsible for the unsettled condition of the industry in a good many quarters.

Second hands are now quoting electrolytic at 26¼ cents for deliveries in July, August and September, and 26 cents for the last quarter. A considerable export inquiry is reported. Exports have been good this month and up to June 22 were 23,925 tons of 2240 lb.

Tin.—Straits tin declined steadily from 44.25 cents on June 12 to 39.25 cents on June 22, but on June 23, showed signs of an upward turn and advanced to 40.25. The consumption of tin is known to be very good, but the amount of spot tin offered for sale has been quite large and consumers would not buy extensively on a declining market. The foreign market has been weak up until June 23, and the weakness was reflected in our market.

Shipments of tin into this country up to June 23 were 4650 tons.

Lead.—The Trust price still remains at 7.00 cents with independents quoting 6.85 to 6.95. For the most part the market has been dull, although large export sales have been reported as recently made.

Spelter.—Spelter has been consistently dull and weak, and spot has declined to 12.00 cents, a drop of almost

2 cents in the last two weeks. The demand for futures which are quoted at 11 cents for September delivery is better than the demand for spot. Earlier deliveries range from 11 to 12 cents.

Other Metals.—Antimony continues dull and is now quoted at 18.50 with very little business done. Aluminum is an exception in the general market and is very strong at 64 cents for Virgin metal. Platinum is quoted at \$75 per oz. with quicksilver at \$76 per flask. Silver is quoted at 65½¢.

Coming Meetings and Events

American Electro-Platers' Society, Cleveland, July 6-8.

National Fertilizer Association, Hot Springs, Va., July 10 to 14.

American Institute of Metals and American Foundrymen's Association, Foundrymen's Convention, Cleveland, Sept. 11-16.

American Institute of Mining Engineers, Arizona, Sept. 18-23.

Mining and Metallurgical Society of America, New York Section, New York, Sept. 21.

Second National Exposition of Chemical Industries, New York, Sept. 25-30.

American Chemical Society, New York, Sept. 25-30.

American Electrochemical Society, New York, Sept. 28-30.

Court Orders Dissolution of Corn Products Refining Company

In the case of the Government versus Corn Products Refining Company, a decision has been rendered by the U. S. District Court.

The quite lengthy decree which had been written by Federal Judge Learned Hand sustains the Government's contention that the Corn Products Refining Co. constitutes a monopoly in restraint of trade under the terms of the Sherman law. The corporation is to be dissolved and a plan for dissolution filed with the Federal Trade Commission within 120 days.

This commission, acting as master in chancery, is to report in due time a plan for disuniting to the Federal Court.

It is expected that an appeal will be taken from the decision.

Water Power Development

Resolution of Joint Conference Committee of National Engineering Societies

The Joint Conference Committee of National Engineering Societies has addressed the following letter to the President, dated June 28, 1916:

"To the President, Washington, D. C.,

"I take pleasure in transmitting to you a copy of a resolution adopted by the Joint Conference Committee of National Engineering Societies at its meeting held on June 15, 1916: 'The Joint Conference Committee of National Engineering Societies believes that the development of the country's undeveloped water power will increase national prosperity; that private enterprise should be encouraged and stimulated to expedite such development; that unnecessary legal burdens should be removed and existing doubts as to the safety of investment eliminated. It commends to the support of engineers all efforts made to secure the fullest publicity as to the underlying facts regarding this subject.'

"The Societies by which this Committee was constituted are: The American Society of Civil Engineers, The American Institute of Mining Engineers, The Amer-

ican Society of Mechanical Engineers, and The American Institute of Electrical Engineers—therefore, it speaks in the name of about 30,000 engineers.

"Yours respectfully,

"CHARLES WARREN HUNT,
"Secretary."

The Joint Conference Committee consists of Calvert Townley, chairman; Chas. Warren Hunt, secretary, and Robert Ridgeway, S. L. F. Deyo, Arthur M. Greene, Jr., D. S. Jacobus, Charles Whiting Baker, J. Parke Channing, Benjamin B. Lawrence, Bradley Stoughton, and William McClellan.

Atlantic City Meeting of American Society of Testing Materials

The nineteenth annual meeting of the American Society of Testing Materials was opened at the Hotel Traymore, Atlantic City, N. J., on Tuesday, June 27. The meetings have been held at Atlantic City for the last ten years.

At the beginning of the Tuesday session the attendance was 250, but at the end of the first day the registration had reached 325. President MANSFIELD MERRIMAN called the meeting to order. The annual report of the executive committee was read by Secretary Edgar Marburg. The chief features of this report were data showing a greater increase in membership in the Society during the last twelve months than in any preceding year (the Society now having 2071 members), an account of the continued good work of the standing committees which form such an important feature of the Society, a discussion of the eligibility of candidates for the nominating committee, and an account of the provisions formally agreed to between the U. S. Department of Commerce and the Society. A resolution was passed that any member who had served the previous year could not serve again on the nominating committee until one year had elapsed, except the three past presidents who automatically become members. The report also included a discussion of the most important matters brought up at meetings of the executive committee during the last two years and a proposal to publish the Year-Book of Standards biennially, instead of once a year. This was voted upon by the Society and passed.

Several reports of standing committees were then read. That on Standing Committees, E-5, was read by Edgar Marburg, chairman; that on Wrought Iron, A-2, by S. V. Hummings, chairman; that on Papers and Publications, E-6, by Edgar Marburg, chairman. The committee on Standing Committees recommended a greater simplicity in the designation of technical committees and standards and also devoted considerable attention to amendments to the Regulations Governing Standing Committees.

Following the committee reports the announcement of the annual election of officers was made. The new officers are as follows:

President, A. A. STEVENSON; vice-president, S. S. VOORHEES. Members of Executive Committee: W. H. BASSETT, JOHN BRUNNER, G. W. THOMPSON and F. E. TURNEAURE.

The Society's new president, who is vice-president of the Standard Steel Works Co. of Philadelphia, Pa., in accepting the chair said that he was the first producer to be elected to the office, and he thought that it was indicative of more cordial relations between the producer and the consumer. He said that it should be his endeavor, however, to conduct the office in a strictly im-

partial manner, and to sustain and forward the work and ideals of the Society.

The afternoon meeting was presided over by General W. H. BIXBY, U. S. A., retired, and was given over entirely to committee reports, on miscellaneous materials. The report of Committee D-3, on Methods of Sampling and Analysis of Coal was read by S. W. Parr, chairman; the report on Committee D-5, on Coal by G. S. Pope, chairman; the report of the Committee on Shipping Containers by B. W. Dunn, chairman; the report of Committee D-11, on Rubber Products, by E. A. Barrier, chairman; the report of Committee D-13, on Textile Materials, by W. D. Hartshorne, chairman. All of these committees had been active and made important recommendations in their reports.

At the Tuesday evening meeting at which the new president A. A. Stevenson was in the chair, an address was presented by retiring President M. Merriman on the work of the committees of the Society. He emphasized that every member of the Society should be gratified at the results of the work of its technical committees. They have thrown new light on many problems of mechanics and strength of materials. Standards have been adopted which have promoted harmony between producer and consumer and which will be of great benefit to the industrial interests of the country. The Society now has thirty-seven committees.

The presentation of papers followed. An account of the same and of the proceedings of the following days is reserved for our next issue.

Industrial Preparedness the Subject of a Commencement Address

At the commencement exercises of the University of Pittsburgh Dr. Leo H. Baekeland delivered the commencement address on industrial preparedness, showing how the preparedness idea has brought forward a set of problems of national efficiency which are interconnected and in which chemistry plays a very important part. Almost every one of these problems is just as important in time of peace as in war. Preparedness against aggression is the best way of insuring the peaceful destiny of the country.

The honorary degree of Doctor of Chemistry was conferred on Dr. Leo H. Baekeland and Prof. J. O. Stieglitz.

Pay for National Guardsmen

In common with a large number of industrial concerns the McGraw Publishing Company, Inc., publisher of "Metallurgical and Chemical Engineering," as well as of "Engineering Record," "Electrical World," "Electric Railway Journal," and "Electrical Merchandising," is continuing payment of their regular salaries to those of its employees who are now members of the National Guard or Naval Reserve and who have been called into the service of the United States. As far as possible the employees will not only be kept on the payroll but their places will be kept open for them until the need of their military service will have ceased.

The good wishes of the whole organization go with them to the front. To those who have to stay at home it is left to continue to preach that the greatest preparedness-problem for this nation still remains to be solved—the problem of efficient nation-wide industrial preparedness.

Coke-Oven Accidents is the title of Technical Paper 151 of the Bureau of Mines, the author being Albert H. Fay. The detailed report shows a gratifying decrease in the number of fatalities and injuries in 1915.

Sources of Metal Loss in Copper Refining

BY LAWRENCE ADDICKS

It is only recently that the general question of metal losses in metallurgical practice has begun to receive anything like the attention it deserves. In any scheme of metallurgical treatment it is always easy to recover say 50 per cent of the value in an ore by some simple direct process. Then improvements are made which will bring the total recovery up to perhaps 65 per cent, but this additional 15 per cent has cost more per unit than the first 50 units. The process gradually develops until the additional complexity brings the operating cost up to a point where further recovery would cost more than the value of the additional metal recovered. It is also soon found that a 65 per cent process can profitably treat a leaner ore, and this adds another variable to the most economical efficiency equation.

Nor is the study of the various sources of metal loss a simple analysis of slag and stack losses although these are among the largest and most obvious sources. While this article deals with copper refining, or the separation of blister copper into fine copper, gold and silver, the method of examination will apply equally well to any other metallurgical process.

Fig. 1 gives a flow sheet of the process under con-

A. Weighing

Scales are about the most precise pieces of physical apparatus we have. In the laboratory when we get a sensitiveness of 0.01 mg. with a capacity of 1 gram, we are working to 0.001 per cent and even lesser ratios are obtainable. In large-capacity scales the best precision obtainable is about 0.01 per cent; that is, if we want to be sure of the nearest pound we must not use drafts exceeding 10,000 lb. Using a 200,000-lb. railroad scale which to-day can be made distinctly responsive to a 20-lb. change in load gives the same precision, but does not equally satisfy a customer who places great stress on individual pounds.

It is, therefore, customary to weigh outgoing copper in 5-ton drafts under such conditions that the refineries have been able to stand upon their weights as final, provided the consignee agrees with the count of pieces. In order to accomplish this, two platform scales are placed in tandem, separate weighers taking readings and comparing figures before passing a lot. These scales are either of the overhung type where the knife edges are overhead and always in sight, or baby railroad scales. The latter are to be preferred as they are free from the obstructions above the floor line

and it is possible to arrange the live platform so that an oncoming car divides the shock between two pairs of knife edges, greatly saving wear.

The standard of weight is furnished by the certification of the U. S. Bureau of Standards of a 50-lb. brass weight as a "Class B or Working Standard." Against this are checked a sufficient number of 50-lb. cast iron weights, adjustable by lead shot, to make up a full-scale load.

These weights are not suitable for every-day use as they afford a great surface for the condensation of moisture, collection of dirt, etc., so a test car loaded with very heavy cast iron weights is checked against them every two or three weeks and this test car is used for daily checks on the merchant scales. In this way it is quite practicable to maintain the desired precision of

FIG. 1—DIAGRAM OF PROCESS

sideration, reduced to its simplest terms. The sources of loss to be considered may be classified as follows:

A. Weighing:

- a. Incoming blister copper.
- b. Outgoing copper.
- c. Outgoing silver and gold.

B. Sampling:

- a. Moisture.
- b. Errors in method.
- c. Salting.

C. Assaying

- a. Assay methods.
- b. Splitting limits.
- c. Assay errors.

D. Slags:

- a. Cupola slag.

1 lb. in 10,000. As identical methods are used for weighing incoming blister and outgoing wirebars there is but small chance of tracing any copper losses to scales in a modern plant.

In weighing the silver and gold the situation is somewhat different. The incoming silver and gold are weighed as blister copper as outlined above, while the outgoing shipments are weighed as bullion. As the gold is always shipped to a U. S. Assay Office whose weights are final, we again come to government standards and have automatically a weekly check against the refinery bullion balance. In one of the large refineries a year's returns showed a difference of but 0.0015 per cent. As a bullion balance is furnished with a set of weights instead of a sliding poise, it is comparatively easy to make mistakes in reading. To lessen this danger it is well to provide a direct-reading spring balance upon which a check to the nearest ounce can rapidly be made.

One of the most fruitful sources of error in weighing lies in the inaccurate taring of cars. Slight differences are bound to occur daily as the oil works out of the bearings but this is not serious. Wear and tear gradually lowers the weight of a car and it should be tared at least every ten days, the weight and date being painted on each side of the car and the rule adopted not to use any out-of-date cars. Similarly a car sent to the shop for repairs should have the weight painted out.

B. Sampling

a. Moisture. It is generally assumed that copper carries no moisture. This question was first raised a good many years ago when some blister copper from Australia which had been more or less immersed in bilge water in transit was found to carry about 0.5 per cent of moisture. Pig copper is quite porous and a quart of water poured on the face of a pig will vanish as if absorbed by blotting paper. Some of the Western smelters are quenching their converter bars in boshes which brings this question up again. About all that can be done in such cases is to make careful tests in a drying oven on certain pigs and apply the correction found to the lots represented. It is evident that a very serious source of loss may pass unsuspected if this is not watched, as the refinery will be accounting for water as copper, silver and gold.

Then we have the question of weighing material that has been exposed to inclement weather. This should never be done, but sometimes it has to be done in order to save large delays, and it is then necessary to impose an arbitrary allowance by agreement. The weighing of hot wirebars does not seem to cause any appreciable error, the rising air currents being negligible. Weighing in the wind is more serious and scales should always be well protected.

b. Errors in Sampling Method. The silver and gold contents in a ton of blister copper may be worth anywhere from \$10 to \$500, although, fortunately for the refiner's peace of mind, there are very few very rich bullions. One hundred dollars per ton would be an ordinary figure, however. It can readily be seen that a small error in determining the true metal contents of blister copper would have an alarming effect upon the refiner's profits. A great deal of experimental work has therefore been done in developing standard sampling methods.

Blister copper usually runs 98 per cent to 99 per cent copper, the bessemerizing of matte having reduced the impurities to small values. The molten blister is poured into open molds and whether or not the copper is afterwards quenched in water it is always allowed to set before being removed from the mold. The pig therefore cools most rapidly on the sides and bottom, the heat be-

ing absorbed by the metal mold, and the last spot to cool is the upper central portion. The silver and gold and other impurities form a complicated series of solid solutions and eutectics with the copper, the richest portion in precious-metal values being the last to solidify.

It is evident that any system of sampling must bear this in mind. Theoretically this would require that when a sampling templet is laid out with a series of holes for drilling, these should be arranged to straddle and not pierce the center line of the pig, as no compensating holes can be drilled in the absolute edge of the piece. Practically this does not seem of great importance as experiments have shown that the richest zone often lies in a ring around the center rather than in the actual center, but it is still wiser to follow the proper practice as different combinations of impurities produce quite different results.

The old-style pig, shaped more or less like a loaf of bread, is now no longer in use except in South America where purchases of bullion are generally made by lot at auction rather than by contract. These old pigs were 6 in. thick and the segregation defied accurate sampling at a reasonable cost. The refineries have succeeded in introducing a bar about 18 by 27 in., $2\frac{1}{2}$ or 3 in. thick, weighing about 300 lb., with just sufficient draft to facilitate removal from the mold and preferably unquenched. This readily yields an accurate sample, stacks well and is heavy enough to be an economical unit in handling.

The Japanese still make a very small pig weighing some 50 lb. These cause heavy sampling and handling costs and are therefore undesirable. Once in a long while copper comes from some out-of-the-way corner of the world which has been cast in pots and these cases call for considerable knowledge and ingenuity on the part of those in charge of the sampling.

A number of other precautions must be taken to secure an accurate sample of pig copper. There must be a sufficient number of holes in the templet—that is, one hole must not represent too large an area, otherwise experience has shown that the sample will be too high. In fact, careless sampling will generally give results on the high side. On the standard pig a quarter templet with forty-eight $\frac{1}{2}$ -in. holes is generally used; this gives an area of about $2\frac{1}{2}$ sq. in. per hole. Each hole is in the center of a rectangle, arranged so that forty-eight such rectangles would just cover one-quarter of the area of a pig. The hole is drilled completely through the pig, each successive pig sample being marked at the next hole in rotation on the templet. In these days of large converter pours it is seldom necessary to drill every pig, one in three, four or even five being sufficient.

It must be realized that there is always more or less dirt on the surface of a pig and also that the set side has an oxide film which may run quite different in values from the body of the metal. It has been proved that decidedly different samples are obtained from a lot depending upon whether the pigs were drilled face up or face down, and further that while for a given brand of pig these differences are generally consistently in one direction, some brands would be the reverse of others. This dilemma has been met by using the so-called top and bottom method. Originally every other pig was turned bottom up, but it was found equally satisfactory to drill every other lot bottom up. No water or other lubricant should be used on the drill as this will tend to oxidize the hot drillings.

A splash sample taken at the smelter by collecting a fraction of the converter pour as shot in water will always show high metal values as against the refinery as such a sample is automatically freed of dirt and slag. For a long time the smelters felt that their splash samples were correct and that the refineries' samples low,

but it has been shown that a properly taken sample at the converter, using no water, can be made to check drill samples on the pig.

Enough has been said to show that sampling methods are a matter of the highest importance in any study of the sources of metal loss, as the refiner has to pay on the values shown by the sample whether or not they exist in the pig.

c. *Salting.* The contamination of a sample during preparation may cause serious errors and consequent apparent metal losses. Nowadays this is seldom done deliberately, although the large laboratories generally have one or two interesting stock tales of this character. It may easily be done unconsciously, however, if silver-refinery slags, doré samples, etc., are handled in the same department as incoming pig copper. The only sure way is to absolutely separate such different classes of work.

C. Assaying

a. *Assay Methods.* In the early days an assay method was supposed to represent the process to be used and the assay value was admittedly lower than the true contents by an amount approximately equal to the expected loss in treatment. In other words, the assay value was the recoverable value. To-day the tendency is to adopt methods which will give the highest result compatible with reliability but which still do not in all cases give full contents. The electrolytic assay for copper does give full value; in fact the chief danger in the handling of this method is that some impurities may be deposited on the cathode and weighed up as copper, to the disadvantage of the refiner.

The so-called uncorrected combination assay for silver in which the bullion is dissolved in nitric acid, the silver precipitated as chloride which in turn is scorified to gather the silver (and gold) into a lead button, the button being cupelled and the resultant lead weighed as silver plus gold, does not give full value of silver by from 2 to 3 per cent. The loss is due to values in scorifier slags, to cupel absorption and to volatilization. The main argument for this method is that when conscientiously run it will duplicate results very closely while there is at present no really satisfactory method of determining the absolute silver contents of foul bullion.

Skill is required in maintaining the proper temperature when cupeling; it must be hot enough to make the button "blick" at the finish, or it is not pure and other elements are weighed as silver; on the other hand it must be cool enough to show "feather" litharge around the edge of the cupel when finished, or the volatilization loss will be excessive.

Mismanagement in the laboratory may easily affect the apparent or financial metal losses. In some cases the "corrected" assay is used, where the losses in scorifier slags and cupels are determined and added, bringing the recovery up to about 99 per cent. Nothing is gained in accuracy and when once the particular bullion is known, the amounts of these losses are very constant and can just as well be allowed for arbitrarily in the refining terms, avoiding the expense and delay of determining daily corrections.

There is no practical way of ascertaining the volatilization loss except by running "proofs" made up with known quantities of silver. With high-grade doré and similar pure material this is satisfactory, but when various impurities are present, they affect the volatilization and a true proof would be a very complicated affair.

In the case of gold the fire assay, where the bullion is scorified direct to a lead button, is used as it gives a higher value than the gold parted from the silver in the combination assay, due probably to filter losses and the oxidation of some gold when dissolving the bullion

in nitric acid in the latter method. This gives a return of about 99.6 per cent in the uncorrected assay. The corrected gold assay is very close to full value.

b. *Splitting Limits.* Were assays absolutely accurate and all laboratories equally reliable, the question of splitting limits would not enter into a discussion of metal losses. As such is not the case it is necessary to agree upon some reasonably allowable difference between buyer and seller within which assays shall be averaged or "split" and beyond which an umpire assayer shall be called upon.

In order to guard against either dishonesty or carelessness several simple precautions should be taken. In the first place assays should be exchanged simultaneously by mail; then all "reassays" to avoid umpires should be forbidden; finally, splitting limits should be made as close as possible. Sometimes the splitting limits are made very close, such as 0.1 per cent for copper, for example, and then only such umpires undertaken as may be necessary to bring the average results for ten consecutive lots within splitting distance.

The umpire should be considered simply as a substitute for one assayer, not as a source of authority. When two assays fall too far apart, the assumption is that one is incorrect and the umpire will determine which one it is. His result should therefore be averaged with the nearest original result unless it is above the higher or below the lower by more than the splitting limit, in which case the sample is pronounced uneven and the two original assays averaged for settlement.

In many cases where wild umpires are reported the trouble with the sample can be rectified by screening out the fines in the sample and then making up a portion for assay with just the proper proportion of fines, the more impure parts of the alloy having been brittle and pulverized under the drill.

It is also well to have two or three competent umpire chemists agreed upon, assigning umpires, as they become necessary, in rotation. This tends to check any inaccuracies in the umpire laboratory.

c. *Assay Errors.*—Assays are subject to three sources of error: (1) those of method; (2) those of procedure; (3) those of calculation, or clerical errors. The first has already been dealt with and may be classed as a voluntary error; the second may be due to carelessness, inaccurate apparatus, such as scale weights or burettes, or impure reagents; the third is more serious than might be imagined and constant vigilance is necessary. Perhaps the most common clerical error is that of reporting double or half the proper value in silver and gold determinations, due to failure to note the fraction of an assay ton taken for assay.

D. Slags

We have now to pass from the apparent losses due to inaccurate accounting for values in the incoming bullion, to the actual metallurgical losses, and the first of these is the loss in the cupola slag. The anode and refining furnace operations produce a certain amount of slag due to the reaction between the metallic oxides formed during scorification in the furnace and silica and other oxides present in the furnace walls and hearth, or introduced as coal ashes blown over from the fire box, or as clay used in luting up the doors, fettling, etc.

In the old days of small furnaces constructed entirely of siliceous material, from 3 to 4 per cent of the weight of the charge was made in slag. In the large modern furnaces constructed partly or wholly of basic or neutral material and with much better fuel economy, the slag made is below 1 per cent.

Theoretically the slag should be a very small item. After a charge is melted air is blown in sufficient to oxidize part of the copper. This cuprous oxide in turn

displaces the impurities by oxidizing them and sending them into the slag. The cuprous oxide is soluble to a certain extent in the molten copper and were no acids present it would be theoretically possible to skim off simply these impurities with a little mechanically entangled copper. The actual slags made run about 45 per cent copper and must be treated in a blast furnace with fluxes such as iron oxide and limestone to make black copper unless a smelting plant is connected with the refinery.

If some sulphur is introduced into this charge a low-grade product running about 94 per cent copper may be made with a slag running below 1 per cent in copper, but this gives a high operating cost in the anode furnace.

If a high-grade black copper is made it is very difficult to get a slag below 2 per cent in copper. Taking a final cupola slag of 36 per cent silica and neglecting the small quantity of silica introduced by the basic fluxes, this means that every ton of silica which is allowed to find its way into the refining furnace slags carries away from 56 to 112 lb. of copper in cupola slag aside from the stack loss in this operation. It is evident therefore that this great source of loss is worthy of the most careful study, to the end that the least possible amount of slag be made at the reverberatories.

E. Stack Losses

a. Anode furnace stacks.

b. Refining furnace stacks.

Not a great deal is known about these losses. The recoveries in flue dust from waste-heat boilers installed in anode furnaces show some 0.07 per cent of the copper treated, rather more of the silver and less of the gold. On the other hand, bag-house tests on the gases escaping from a high direct stack have shown less than this amount. The composition of the bullion under treatment has doubtless much to do with these losses, as the recoveries on furnaces treating cathodes are much less, due partly to less working of the molten charges and partly to the absence of volatile impurities which always promote metal losses.

c. *Silver refinery stacks.*—The anode slimes consist of the insoluble impurities contained in the anode and run 30 per cent to 40 per cent in silver. The copper is mostly leached out as sulphate and the slimes are then melted and subjected to a series of oxidizing operations until a high-grade doré is obtained.

In general about 1 per cent of the silver treated and about 0.1 per cent of the gold is recovered by various means in the flue system and great progress has been made in the last ten years in this practice.

Until the Cottrell system of electrostatic precipitation was successfully applied to treating these gases, the opportunities for serious undetected losses were very great and even now there is no point in a metal loss investigation which needs more careful watching.

The great difficulty is that the actual losses made are clearly discernible only after several years, as the results from single yearly inventories are always more or less clouded by anode furnace bottom absorptions which vary from year to year, and the punishment comes so long after the crime that it is very easy to be lax to the immediate benefit of apparent operating costs. Molten silver should be handled like a volatile liquid.

d. *Cupola Stack.*—This loss should be relatively small, as the operations are on a small scale and the charge in reasonably good physical condition. A proper dust chamber should be installed, however.

F. Process Losses

a. *Silver and gold in outgoing copper.*—This loss is a perfectly definite one shown by daily assays. In gen-

eral the loss runs from 0.5 to 0.8 per cent of the silver and gold present in the anodes. In the case of low-grade anodes this is not serious, but when rich material is being treated this loss becomes quite an item. The loss is due to slimes adhering to the cathode and is affected by the current density, the volume of circulation of the electrolyte, and the degree of refining given in the anode furnace.

b. *Silver in outgoing gold.*—The Government does not pay for the silver in gold deposited unless the fineness is low enough to require refining. In the latter case the refining charges imposed greatly exceed the costs of refining before shipment. The net result is that any silver contents are not paid for and therefore constitute a metal loss. This loss should not exceed two or three parts per thousand.

c. *Gold in outgoing silver.*—Any gold in outgoing fine silver is, of course, a total loss. It should be possible to keep this loss down to 0.1 oz. per ton of silver.

d. *Minor losses.*—These comprise values lost in any by-products sold, such as nickel sulphate, selenium, platinum, etc., and the value of assay samples sent out without credit, etc. These sources of loss are relatively unimportant but should not be overlooked.

e. *Process margins.*—These are negative losses or gains due to receiving more metal than accounted for, or to shipping less, due to trade customs. In copper there is no assay margin, but there is a gain of about 0.07 per cent due to the fact that wirebar copper runs but about 99.93 per cent copper, while it is credited as 100 per cent against incoming copper received on actual contents.

In the case of silver the uncorrected combination assay allows the refiner about 2.5 per cent margin while on shipments of fine silver, although the assay used shows true contents, a fineness of 999 is considered a 100 per cent delivery. With gold there is a margin of about 0.4 per cent in the incoming bullion from the fire assay used, but no margin in the outgoing fine gold.

G. Handling Losses

a. *Wind losses.*—Wind does not cause as much trouble in a refinery as in a smelter, owing to the nature of the material handled. If the atmosphere were absolutely quiet, however, it is conceivable that the fume losses from stacks would settle down within the confines of the plant. Dust collected from the roofs of the buildings is always high in grade although very small in quantity. I have a memorandum of a sample of so-called dust swept up near a refinery furnace building which ran 65.81 per cent Cu, 49.8 oz. per-ton Ag and 3.41 oz. per ton Au.

b. *Theft.*—A refinery is always subject to losses by pilfering and a most thorough system of patrol, passes, etc., together with a policy of prosecution of all cases detected is necessary to hold this in check. Copper is a very easy metal to sell as junk and systematic carrying away of small quantities in lunch pails, etc., may run into surprising amounts. In the silver refinery it is customary to bond the employee and to have a double set of dressing rooms with different clothes for work and for outside wear, the men passing stripped before a watchman from one room to the other. One assistance in the detection of silver and gold thefts lies in the fineness of the products. When a man offers 999 silver or 24 carat gold for sale he at once arouses suspicion.

c. *Solution losses.*—Although the day has passed when electrolytes were purified by running a proportion to the sewer at regular intervals, there is still plenty of opportunity for loss in the handling of solutions.

It is very difficult to keep the electrolyte with its free sulphuric acid confined to the circulating system on ac-

count of tank leaks, overflows, etc., and it is even more difficult to build a permanent water-tight acid-proof floor under these tanks.

Some of the earlier refineries suffered severely from such losses and I know one plant where it was possible to dig a well anywhere in the vicinity and pump out water which gave a profitable copper recovery when passed over scrap iron.

One good way to keep track of losses from this and similar sources is to keep a careful record of sulphuric acid movements in the solutions. Serious acid losses point at once to equivalent copper solution losses. In plants where waste liquors are worked up by cementation upon iron there is an additional opportunity for loss in undertreated waste liquors.

d. Soil losses.—Where a plant is unpaved there is always more or less metallic material ground into the earth and in a smelting plant the top soil becomes in time very good ore. In fact some of the smelters have been smelting this material during the recent high metal prices. In a refinery there is not the same opportunity for loss owing to the nature of the material handled and such a loss should be negligible except in the case of solution losses mentioned above and that of slimes losses taken up below.

e. Slimes losses.—Mechanical losses of slimes could, of course, be assigned to the several sub-headings preceding, but the matter is so important that a separate paragraph has been reserved for their discussion.

Slimes originate in the tank house. They are periodically sluiced down into a screening tank whence they are usually transferred by pumping to a receiving tank in the silver refinery. A certain amount is carried out in the cathodes, a matter which has already been taken up. More or less adheres to the anode scrap when it is drawn and is removed as thoroughly as possible by scrubbing or by high-pressure water-sprays before the scrap is sent to the anode furnace. Any carelessness here may result in wind and soil losses in transit or up the stack during melting.

Tank leaks in the tank house carry considerable quantities of slimes to the cellar floor. While most of these values are recovered by washing the floor, some is absorbed and the floor material has to be smelted whenever extensive repairs are made.

In the silver building the slimes of necessity get spilled around to a certain extent and as boiling operations are conducted in this department the steam makes a sort of paste with them and care must be taken that all unnecessary walking in and out of this department be avoided, and that proper means for wiping shoes be provided. The shower baths used by the workmen should drain into the general wash water system.

The very best possible floor must be provided in this building. During some changes in one of the silver refineries some old foundations yielded up an absorption of 17,000 oz. of silver and 200 oz. of gold.

The slimes before melting have the appearance of black mud and it is very hard to get workmen to handle them with the care they instinctively give to the silver sponge and other metallic products produced later.

From the foregoing it will be appreciated that constant thoughtful attention in a great many directions is necessary to make a minimum metal loss. As the precautions all cost money it raises the question whether the additional saving due to them pays. The answer to this is that it is only by constant schooling in all these precautionary measures that men can be trained to be really careful when they are on their own responsibility and not under observation. For this reason the liberal use of white paint and many other seeming extravagances are justified. The same rigid care and supervi-

sion in the weighing, sampling, and assaying is required as in the control of slag and cathode losses, and careful attention must be given on general principles to all the apparently insignificant sources of indefinite loss.

The Formation of Aromatic Compounds from the Cracking of a Gas Oil

BY GUSTAV EGLOFF AND THOMAS J. TWOMEY

The commercial yields of aromatic compounds from the thermal decomposition of a gas oil at atmospheric pressure have not been given in the literature, although many processes as the Pintsch gas and oil gas machines have been using gas oil for years, forming the products aliphatic and aromatic hydrocarbons, permanent gases and carbon. The enormously increased demand for the substances benzene and toluene, due to the European war, emphasizes the necessity of having clear-cut information as to the number of gallons of benzene and toluene which would be produced from 100 gal. of gas oil used. It is hoped that this research will add to our information as to the yields of the aromatic hydrocarbons, benzene and toluene, from the cracking of a gas oil at atmospheric pressure and various temperatures at constant rate of oil flow into the cracking area.

The gas oil was pumped from a storage tank, passing through a calibrated oil meter into a gas-heated steel tube of 11.6 ft. in length and 8 in. in diameter, which was held at the temperature of the experiment. The gas oil was immediately vaporized in the upper portion of the tube, and the vapor passing through the heated zone was cracked into lower boiling aliphatic and aromatic hydrocarbons, permanent gases and carbon. The cracked vapor in part passes downward out of the sphere of the reaction through a coil condenser, the balance condenses in the air-cooled carbon pot at the bottom of the steel tube. The cracked oil from the condenser and carbon pot are mixed and a sample taken for analysis.

The oil used is what is termed commercially a gas oil derived from Pennsylvania crude petroleum. The gas oil had a boiling range of 90 per cent between the temperatures 200 deg. C. and 350 deg. C. The specific gravity of the starting oil at 15.0 deg. C. was 0.841, using a Westphal balance. The distillation was made with a Standard 100 c.c. Engler flask.

Temperature	Per Cent by Volume	Specific Gravity
0°—200° C.	3.9	
200°—250° C.	8.9	0.768
250°—300° C.	46.2	0.823
300°—350° C.	35.4	0.849
Residue	5.6	

In each experiment 20 gal. of oil were used.

The oil was cracked at five temperatures, 1100 deg. Fahr., 1200 deg. Fahr., 1300 deg. Fahr., 1400 deg. Fahr. and 1500 deg. Fahr. The gallons of oil flow into the cracking area was held approximately constant at 12 gal. per hour. In each experiment the number of gallons used was 20, and was measured with an oil meter which had been calibrated. The temperature of the reaction was determined by the use of a pyrometer, and registered the temperature upon the outside of the steel tube. Very careful temperature control was maintained as far as practical. The temperature variation was never greater than plus or minus 10 deg. Fahr.

The analysis of the cracked oil was conducted according to a method devised by the authors.¹ The procedure was to distill the cracked oil by use of an efficient fractionating column to 170 deg. C. This cut is refrac-

ated and analyzed for its benzene, toluene and xylene content by distillation cuts and specific gravity.

The specific gravities of the cuts were taken by means of a Westphal balance at 15.0 deg. C.

Experimental Data

The experimental data follows in the form of tables and graphs.

Table 1 and Fig. 1 show the effect of temperature on the per cent of recovered oil and specific gravity of recovered oil.

FIG. 3—THE EFFECT OF TEMPERATURE ON THE FORMATION OF BENZENE, TOLUENE AND XYLENE ON THE BASIS OF OIL USED

Discussion of Experimental Data

A. THE EFFECT OF TEMPERATURE ON THE PER CENT OF RECOVERED OIL AND SPECIFIC GRAVITY OF RECOVERED OIL

A paraffin base oil when subjected to thermal decomposition in the vapor phase yields permanent gases, carbon, and a liquid which is widely different in constitution from the original starting oil. It contains some high molecular weight paraffins; lighter molecular weight paraffins; olefins and aromatic hydrocarbons of the type benzene, toluene and xylene.

From Fig. 1 it will be noted that as the temperature increases the decomposition of the oil increases, most markedly between the temperatures 1200 deg. and 1300 deg. Fahr.

The specific gravity of the cracked oil increases with increase of temperature. At 1100 deg. Fahr only a slight difference will be noted from the gravity of the starting oil. This would indicate that only a small amount of cracking takes place at this temperature. The greatest change takes place between the temperature limits of 1200 deg. and 1300 deg. Fahr., which are also the temperature limits which give the highest decomposition of the original oil.

B. THE EFFECT OF TEMPERATURE ON THE FORMATION OF BENZENE, TOLUENE AND XYLENE IN THE RECOVERED OIL

In the thermal decomposition of gas oil the formation of xylene proceeds more rapidly than either benzene or toluene at the lower temperatures. As the temperature is increased to 1400 deg. Fahr. the benzene and toluene content of the recovered oil increases rapidly, whereas

the xylene falls off considerably. The maximum amounts of benzene, toluene and xylene are: 8.5 per cent benzene at 1500 deg. Fahr.; toluene, 8.5 per cent at 1400 deg. Fahr., and 6.8 per cent xylene at 1500 deg. Fahr.

C. THE EFFECT OF TEMPERATURE ON THE FORMATION OF BENZENE, TOLUENE AND XYLENE ON THE BASIS OF OIL USED

Commercially the interesting and most important fact of cracking gas oils at present are: how many gallons benzene, toluene and xylene can one make from 100 gal. of gas oil? The maximum formation of benzene was found to be 3.3 gal. per 100 gal. of oil used. Toluene yield was 3.2 gal. and xylene 2.5 gal. for each 100 gal. of oil used. In other words, 9 gal. of valuable aromatic compounds from 100 gal. of paraffin-base gas oil.

D. THE EFFECT OF TEMPERATURE ON THE DISTILLATE TO 170 DEG. C. AND THE SPECIFIC GRAVITY OF THE DISTILLATE

The light oil distillate to 170 deg. C. contains all of the benzene, toluene and xylene. It will be noted that as the temperature increases the per cent of distillate to 170 deg. C. increases to a maximum and then decreases. The gravity also increases with increase of temperature, and indicates the greater decomposition of the paraffin hydrocarbons to aromatic compounds.

E. THE EFFECT OF TEMPERATURE ON THE SPECIFIC GRAVITY OF THE BENZENE, TOLUENE AND XYLENE CUTS

The specific gravity of the cuts of benzene, toluene and xylene indicates the relative freedom from like boiling point hydrocarbons of the paraffin series, which

TABLE IV—THE EFFECT OF TEMPERATURE ON THE DISTILLATE TO 170° C. AND THE SPECIFIC GRAVITY OF THE DISTILLATE

Temp.	Per Cent to 170° C.	Specific Gravity
1100° F.	20.8	0.770
1200° F.	25.8	0.788
1300° F.	28.7	0.823

1100° F.	0.734	0.787	...
1200° F.	0.740	0.798	0.816
1300° F.	0.796	0.840	0.850
1400° F.	0.850	0.866	0.875
1500° F.	0.874	0.864	0.867

FIG. 5—THE EFFECT OF TEMPERATURE ON THE SPECIFIC GRAVITY OF THE BENZENE, TOLUENE AND XYLENE CUTS

cannot be removed by any physicochemical means. Trinitrotoluene and phenol can be readily made from the toluene and benzene which are formed from the decomposition of a paraffin-base gas oil.

SUMMARY

1. The greatest decomposition of the gas oil used takes place between the temperatures of 1200 deg. Fahr. and 1300 deg. Fahr.

2. The maximum amounts of benzene, toluene and xylene in the recovered oil are: benzene, 8.5 per cent at 1500 deg. Fahr.; 8.5 per cent toluene at 1400 deg. Fahr., and 6.8 per cent xylene at 1500 deg. Fahr.

3. It has been shown that at atmospheric pressure and 1400 deg. Fahr. in a steel tube 11.6 ft. in length and 8 in. in diameter, that 100 gal. of the gas oil used will produce 3.3 gal. of benzene, 3.2 gal. of toluene, and 2.5 gal. of xylene.

4. It has been shown that the benzene, toluene and xylene, relatively free from paraffin hydrocarbons, can be produced from the cracking of a gas oil.

Electrochemical Possibilities of the Pacific Coast States as Compared with Those of Sweden and Norway*

BY J. W. BECKMAN

To some of us the word electrochemistry has a mystic charm; it produces visions to the mind's eye of turbulent streams and waterfalls in the midst of peaceful forests, and also the vision of the electric furnace with its sputtering frenzy. It is a wide step from the waterfalls in the woods to the wild roaring of an electric furnace, but we all know that they stand in intimate relationship to each other. The power of the impetuously falling water is harnessed and transferred often hundreds of miles, silently and calmly over a wire, only to be let loose at the other end in often a wild though conquered shape, to produce products which a complex civilization has learned to be dependent upon.

To-day there may be dreamers who have visions of cheap electric power being produced in a way other than by water power. It may be possible to do this, but for the big electrochemical industries of to-day, and of the future, hydraulically produced power is and will be used. Therefore, the most important raw materials of all electrochemical industries is an abundant amount of water seeking a lower level. Few locations offer conditions favorable to the harnessing of water for industrial purposes, and as a rule the mountainous countries are the water-power producing localities.

Lands that are known as hydroelectric power producers are various mountainous sections of Southern Europe as well as Sweden, Norway, and Finland in Northern Europe. The Western sections of the North and South American continents are, together with New Zealand and a few other localities, favorable to hydroelectric power developments.

It may seem strange to compare Sweden and Norway, countries old in the civilized history of the world, and from our point of view located on the globe practically at the North Pole, with the three Pacific Coast States, California, Oregon and Washington, but I believe there are many similarities, in spite of difference in relative position on the globe, that are in many respects quite startling.

I beg you to note that Sweden and Norway are about as large as the three States of Washington, Oregon

and California. The population in Sweden is about five millions, and the three coastal States contain practically the same number.

Sweden has large sections along the coast which are comparatively flat, consequently the water power sites are located mainly inland, much the way conditions are on the coast. One-half of Sweden is wooded, while half of these three States is under timber.

Geologically the conditions are very different. Sweden is practically all of very ancient geological formation, while the coast is, as we all know, of comparatively recent formation.

In a general way conditions in Norway are similar to those in Sweden. The land is heavily timbered and filled with inaccessible mountains and valleys. In many places the streams drop right into the ocean, making power developments possible on tidewater, similar to the possibilities on our own coast in British Columbia and Alaska. The geological formation in Norway is of the same age as in Sweden. Norway has about three million inhabitants, making a total of eight million inhabitants on the Scandinavian Peninsula.

The electrochemical possibilities in Sweden and Norway are great for two reasons only—one is abundance of cheap power, the other is comparatively cheap labor.

Seven and one-half million horsepower are available in Norway at present, of which one-half million is developed, and an additional million horsepower is under development. When this power is developed it will amount to about 20 per cent of all available power.

The largest present, single operating installation is at Rjukan, where 131,000 hp. are developed and at the same place 119,000 hp. are being developed, which is the largest power development under way there at present.

There are two developments possible in Norway, each for 240,000 hp., but neither of them is even projected to be developed. Many of the installations are in the interior and inaccessibly located, involving special means of transportation to reach them, often through sections of the country where power transmission is impossible, partly due to the nature of the country, and also due to climatic conditions.

However, in Sweden conditions are materially different. The heads are comparatively low and the nature of the country makes long transmission lines possible. The available power in Sweden is 6.2 million hp., of which at the present time 900,000 hp. are developed, about 15 per cent of total available power.

The largest single development in Sweden is that of the Swedish government at Trollhättan, in the Southern part of the country, where a total of 80,000 hp. is obtainable. The greater part of the Swedish developments are low-head and small-capacity plants.

If the power situation be considered in the Pacific Coast States, it will be found that there are available about 11,000,000 hp., of which 7 per cent or 831,000 hp., have been developed. Most of the developments are high-heads, 500 ft. or more—a few exceptions there are—and among the most noted proposed low-head developments on the Pacific Coast is The Dalles development on the Columbia River, where about 800,000 hp. could be delivered. More than half this amount could be supplied twelve months of the year. The remaining power could be counted on for eight to eleven months of the year.

The Great Western Power Company is, in spite of having developed some 100,000 hp., still able to develop some 500,000 hp.

On account of local and climatic conditions in the

*A paper presented before the San Francisco Section of the American Chemical Society.

coastal states, long distance transmittal is easy and comparatively cheap.

As the population is centered in the large valleys and along the coastal districts, the necessary length of power lines from generating stations, located in the mountains, to the consuming districts, are comparatively short, and the lines with few exceptions do not exceed 200 miles.

The cost of hydroelectric power is really a question of bookkeeping, and since each individual power plant has its pet way of calculating costs, it is impossible to compare the average power costs given with each other, not knowing how much, or how little, they include, what the interest rates are, etc. When a standard accounting method is adopted by all power plants all over the world, then the comparing of cost, per horsepower, may have some meaning.

When an industry develops its own power source, the bookkeeping method can hide absolutely the actual cost of the power. On this account I am extremely sceptical as to the low figures quoted for the power some industries utilize in Norway.

The prices for power obtainable on this coast close to, or at the power site, do not vary materially from those in Sweden and Norway.

The prices in those countries are from about \$6 per horsepower-year, and up, provided large blocks of power are taken. In Norway with higher head developments the minimum price may be somewhat lower.

Compare these prices with that of less than \$10 per horsepower, quoted by the State of Oregon for power from the projected development at The Dalles, and I believe it will be agreed that cheap power is available here, as well as in Sweden and Norway.

Only recently the Great Western Power Co. has entered into contract with an electrochemical company, for large blocks of power on tidewater at a rate that is as good as that which is obtainable at Niagara Falls. Niagara Falls is 500 miles from tidewater, which means a long rail haul. Power on San Francisco Bay at the same rate, means large savings in the way of transportation charges, etc.

The idea that there is an abundance of cheap labor in Sweden and Norway is to an extent a fallacy. Emigration is continuously draining the working stock of the people, and although the average daily wage is about \$1 to \$1.25, there is not a superabundance of labor, and the industries are often handicapped. Of course, in the more specialized industries, as the electrochemical, the price for labor is somewhat higher.

Compared with the cost of labor on the Pacific Coast, the Scandinavian prices are low. But the ultimate cost of producing electrochemical products, I believe, is no higher there than here, due to higher cost of raw materials there than we have to pay.

What, then, are the industries that have brought Sweden and Norway to the front in the eyes of the world as countries that take a foremost position in the electrochemical industries?

When artificial nitrogen fertilizers are mentioned, Norway with its nearly 300,000 hp., exclusively devoted to that industry, looms up. Calcium nitrate and calcium cyanamide are both products made in Norway; the latter is also made in Sweden. The raw materials for these products are: cheap power, the nitrogen of the atmosphere, and limestone. In case of the cyanamide, coal is also needed. In Sweden and Norway, plentiful, cheap power is available, though not always in accessible places as the large developments at Rjukan, in Norway show, located as they are in the most impenetrable part of the mountain fastness. Nitrogen is abundant; lime-

stone is accessible, in some cases, though involving considerable haul by rail or water. The coal is all brought in from England, which means expense of handling and in addition duty on the importations.

The Pacific Coast States are in this respect as favored in many instances, as the countries of the Scandinavian peninsula. Take, as an example, the projected development at The Dalles; deep-water navigation is possible up to and beyond the proposed power site; limestone from Washington could be brought in cheaply, quarried as it is right on tidewater; coal from China, and eventually from Alaska could also be brought in and water transportation would be available for the finished product.

Similar conditions can be found at other localities on the Pacific Coast.

What has been said in regard to the fertilizer industries applies equally well to the carbide industries. Sweden consumes some 20,000 hp. annually in carbide manufacture and Norway, though I have no definite figure, consumes considerably more at the large works at Odda.

The Swedish iron is famous and well known over the world. There was a time, however, until quite recently that Swedish iron was beginning to lose its reputation. Scarcity of charcoal followed the increasing numbers of shaft furnaces in operation until gradually some of the iron masters of Sweden began to substitute coke with charcoal and the common coke pig iron was obtained with a result that the long established position held by Swedish iron in the markets of the world was fast slipping away. To-day, though, it is possible to increase the number of shaft furnaces in Sweden to three times as many as at present, without being obliged to use coke.

The reason is the introduction of the electric shaft furnace, in which two-thirds of the charcoal used for heating the charge in the furnace are replaced by electric heat. As the earliest blast furnaces were built in Sweden, so also Sweden first successfully solved the electric shaft furnace.

The iron industry of Sweden is located in a narrow strip 70 miles wide and 140 miles long approximately, the distance from Oakland to Sacramento. This small section of the country has brought, through its iron, fame to Sweden. As time goes along and the old blast furnaces have to be replaced with new, never again will an old-type furnace be placed in operation. Electrical shaft furnaces will be installed instead. There are now over a dozen of these furnaces in operation in Sweden turning out close to 50,000 tons of iron per year. The raw materials needed in electric shaft-furnace operations are cheap power, high-grade iron ore, good limestone and an abundant supply of charcoal.

Close to 1,000,000 tons of charcoal are burnt in Sweden annually, a great part of which is used in the iron industries. The charcoal is burnt all over the country and shipped into the iron-producing district by rail.

The greater part of the charcoal is produced in the old-fashioned way of heap-burning, though there is a strong tendency at present to replace the heap-burning by the large-unit by-product charcoal ovens, of which there are over twenty plants installed and operated. In this connection let me mention that at the Panama-Pacific Exposition there was a very excellent exhibit in the Swedish Building, of raw materials used and finished products obtained from one of these by-product plants.

Norway is also heavily timbered, but due to very great transportation difficulties charcoal is not produced in such quantities there, nor do I believe they have any electric shaft furnaces in operation.

The iron ore is abundant in Sweden. Some has to be concentrated, since high contents of silica mean an excessive power consumption in the electric shaft furnace. The Northern ores from the large famous deposits near the Arctic circle average close to 70 per cent iron, and so do the concentrates from the more centrally located deposits.

Limestone is available though not always in close proximity to the shaft furnace plant.

Power is very often obtained from small hydroelectric developments, where enough energy is generated to operate a single furnace or purchased from a generating station.

What then are the conditions on the Western coast of the United States that would suggest the possibility of an iron industry growing up similar to that of Sweden.

The three coastal States have practically as much timber land as Sweden; the actual board measure would be much to the advantage of these States, since, due to climate and other conditions the growth in Sweden is quite light. Incidentally it is of interest to realize that Washington, Oregon, and California to-day contain about one-half of all the timber lands in the United States. There are twenty-eight hundred billion feet of timber in the United States, while these three States have of this amount thirteen hundred billion feet.

By-product charcoal plants, close to the large lumber operations, should at present not only be the wise policy for lumber operators to follow, but should also give a good revenue from what at present is a decided nuisance and often a menace, and supply the needed charcoal for iron reduction.

It would take many years to develop 1,000,000 tons of charcoal per year on the West coast, but it is interesting to note that under conditions considerably adverse to our own this has been accomplished in Sweden.

Limestone is abundant all through the States, the quality of which is suitable for smelting purposes.

Iron ores of varying qualities, some of the highest purity, and others less pure, are available at many points in California and in adjoining States.

Power close to power sites and in the timbered districts, where charcoal could be cheaply made, is obtainable at prices which will make electric shaft-furnace operations not only successful, but financially profitable.

Norway and Sweden produce small amounts of ferroalloys. The raw materials have to be imported. As an example, chrome ore is brought in from New Zealand.

The raw materials for such industries are right at hand in these States and can be had, in many cases, practically at no cost compared with prices paid for similar raw materials brought into Sweden and Norway.

Norway produces some aluminium from ore, part of which is imported and part is obtained from local deposits.

The Pacific Coast States have a very large supply of practically pure aluminium oxide awaiting treatment in waste piles, the aluminium oxide being a by-product in the potash production from alunite. Utah is one of the States where this by-product is produced.

Sweden produces considerable quantities of sodium and potassium chlorate. The raw materials have to stand heavy freight charges as they are imported from Germany. This is also the case in reference to salt used in the manufacture of caustic soda and bleach.

We are favored here by salt, which is readily available. It may be of some interest to know that a caustic soda and bleach plant is being built on San Francisco Bay.

Potassium chloride is to be had from Searles Lake,

we hope at no very distant date. Meanwhile we may be able to get this salt from various waste materials available on the Pacific Coast, which are now being absolutely neglected.

An industry of special interest developed in Sweden is the electric reduction of zinc. Not less than 18,000 hp., producing close to 4000 tons of zinc per annum, are consumed in this industry. Ores containing both lead and silver, as well as zinc, are used in recovering the values.

Many of the ores of the West, which are now deemed practically worthless due to zinc content, could be advantageously treated in the electric furnace on the Pacific Coast.

An industry can never be a success if there is no market for its products.

Sweden and Norway together have a population, as mentioned before, of about 9,000,000 people, and since the greater part is a rural population there is a comparatively small demand for manufactured products. Therefore, foreign markets have been sought for the products of the industries.

There is no part of the globe that is not in some way dependent on products made in Sweden and Norway. This wide market field has been developed through necessity and necessity has forced co-operation. Commercial agencies have been formed in foreign ports through which everything from Swedish lumber, sewing machines to electrochemical products have been sold. The different manufacturers have maintained these sales agencies jointly and consequently the selling cost in foreign countries has been brought down to a minimum for the various products.

The nearby European markets are severely competitive, but they have been entered successfully. This has been possible for two reasons: quality of product and price of product.

Sweden and Norway, the latter especially, have learned the art of handling tramp steamers. Due to this fact freight rates for products reaching foreign markets have been brought to a minimum.

It is equally possible for electrochemical industries, or, in fact, any industry on the Pacific Coast to penetrate foreign markets. We can reach from this point over one-half of the world's population by going West and South. Some of the markets are small, but are bound to grow, and if we miss the present opportunity somebody else will step in and collect the harvest which legitimately belongs to us.

The large electrochemical developments in Norway are financed by international capitalists, involving various complex problems, while here, if the needed capital cannot be procured on the coast, projects may be jointly financed by local as well as Eastern capital. This involves at the most a trip East with none of the complications that go with the use of foreign capital.

The Pacific Coast is endowed with raw materials that may in time revolutionize some of the large industries; take, for example, oil so abundantly present in California.

Doesn't it seem like the intention of fate that large high-grade iron ore deposits, hydroelectric power and oil have been placed side by side? Can't we conjure up a new type of iron-reduction process where the iron is obtained from the ores by means of electric heat combined with the carbon and hydrogen in the oil, as reducing agent? I feel certain that the day will come when the Pacific Coast will be a factor in the iron markets of the world, due to the presence of these three agents.

Norway has about 500,000 and Sweden practically 150,000 hp. utilized in electrochemical and electrometal-

lurgical industries. These have not grown over night. On the contrary, careful and faithful pioneer work had to be done not only in the laboratories, but among the population, and also in the Council Chambers of the nation. An electrochemical atmosphere has been produced; the layman has been brought face to face with it in perusal of his daily paper and gradually the population has grasped the fact that (though the details are perhaps hidden to the layman) electrochemistry is one of those mystic shrines by which, if treated with the correct signs known only to a few, new developments and wealths are produced.

We need an electrochemical atmosphere on the Pacific Coast. Up to the present time gold mining has been the atmosphere. Everybody knows what a placer mine or a gold dredge is; the papers are full of it. The large State universities of the coastal States as well as the daily papers, can assist in bringing this electrochemical atmosphere here.

Without fear of being refuted I will say that the Pacific Coast has more potential wealth in its 11,000,000 hp. of water power, of which 93 per cent goes to waste to-day, than all the gold that ever was mined or is still to be mined in these States.

Sweden and Norway are to-day looked upon as electrochemical centers. The Pacific Coast, I believe, will, within the lifetime of most of us, be looked upon as one of the large electrochemical centers of the world due to our being favored with abundant hydroelectric power and the varied and important raw materials needed in these industries and due to the enterprise of the men of this coast.

Electrochemistry is a young science in its present development compared with other sciences. The electrochemical industries are consequently young men's industries. Therefore, young men are needed, men with the pioneer's optimistic resourcefulness and courage. But this alone is not sufficient; they need a special education which the large universities of this coast are bound to give if they are not already giving it to their students.

With the power, the raw materials and the men the Pacific Coast holds a mighty future in the field of electrochemistry.

Great Western Power Company,
San Francisco, Cal.

The Draeger Oxygen Apparatus Co., Pittsburgh, Pa., have placed on the market a new pulmator which is designed type "B." A pamphlet has been issued by the company describing the many advantages of this new type.

Increase in Japanese Zinc and Aluminium Industries.—Considerable activity is being manifest in Japan in the zinc and aluminium industries. According to Commerce Reports the recent development of the zinc-refining industry has brought considerable increase in the output of zinc ores. The total output is expected to be more than 10,000 tons per year, as compared with 40,000 tons before the war, when the refining mills were mainly dependent on supplies from Australia. The Japan Aluminium Manufacturing Co., which has recently been floated by Tokyo, Osaka and Nagoya capitalists with capital of 1,000,000 yen (\$498,500) is building a factory at Rokuga-mura, a suburb of Nagoya. It is to be completed in the course of July, and operations are to be started in August. The management of the company intends at the start, the Japan Chronicle states, to turn out about 250 tons a year. The Japan Aluminium Co. intends ultimately to increase the capital to 10,000,000 yen (\$4,985,000) with the object of turning out 25,000 tons a year, that is, the total quantity needed in Japan.

The Rate of Driving the Blast Furnace

BY J. E. JOHNSON, JR.

One of the most important items in the control of furnace operation is the rate of driving. This is to say, how much iron we should attempt to make per day from a given furnace which depends, other things being equal, upon the amount of coke we burn and that in turn on the amount of blast we blow per unit of time. The best rate must be determined with reference to two sets of considerations, one technical and the other commercial.

The technical ones are: first, effect upon the regularity of the settling of the charge; second, the effect upon fuel consumption; third, the effect upon the power required for blowing; fourth, the effect upon flue dust lost; fifth, effect on the life of the lining. The commercial ones are: first, the effect upon profit, since other things being equal the annual profit is proportional to the tonnage produced; second, the effect upon costs other than fuel cost, principally labor and overhead, since these costs per ton are, other things being equal, inversely proportional to the output; third, the effect upon the value of the power consumed for blowing. This distinction between technical and commercial considerations is more or less arbitrary since all these considerations are partly one and partly the other, but the distinction is permissible to facilitate the more technical treatment of the subject now, leaving commercial considerations to be discussed in a later chapter.

Effect on Descent of Charge

The effect of the rate of driving upon the regularity of the descent of the charge is placed first because it is of capital importance and affects every other item. Without regularity of descent of the charge we cannot steadily maintain the production of the most profitable grades of iron, we cannot secure the maximum monthly output, we cannot, above all, secure highest fuel economy, and, finally, without it we cannot keep our flue dust losses within any reasonable limits, when running on fine ore.

Reverting to the article on the physical action of the blast furnace it will be seen that the resistance to the passage of the gas rises as the fourth power of the quantity of blast blown, so that from our pressure chart it can be shown that while a 22 x 90-ft. furnace, blown with 45,000 cu. ft. of wind, requires about 13 lb. blast pressure, the same furnace blown with 55,000 ft. of wind would require about 17½ lb. pressure. As pointed out in that article, these figures are both probably a pound or so low, but this fact only exaggerates the difference.

From the conclusions reached as to the relatively accurate balance between the weight of the charge and the forces supporting it, it will be seen that a change like this of almost 50 per cent in blast pressure might easily result in disturbing the floating equilibrium between weight and resistance, and so result in hanging the charge column or some portion of it lying above a tight zone. This would result in slipping, with all its attendant evils—reduced output, poor and irregular quality, higher fuel consumption, and all the rest—these results, of course, being in some rough degree proportional to the seriousness of the slipping caused.

The Effect of the Rate of Driving on Fuel Consumption

This is a very complicated matter. In the early nineties, when outputs were on the average less than half of what they are to-day, it was supposed that the maximum rate of driving, consistent with economy, had been reached. In the interval which has elapsed since,

we have seen a much more rapid rate of driving accompanied by a much higher fuel consumption, but this has been succeeded in more recent years by a marked reduction in fuel consumption, so that the best of to-day is better than that of any past time, irrespective of the rate of driving.

In order to make an adequate comparison it is necessary to have a measure of the rate of driving. This is quite generally taken as the number of pounds of coke burned per hour per square foot of hearth area, so that if a furnace with a 16-ft. hearth were burning 480 tons of coke per day, that is, 20 tons of 2000 lb., or 40,000 lb. per hour, the area of a 16-ft. circle being 200 sq. ft., the rate of combustion is 200 lb. per square foot per hour.

It is commonly considered that 250 lb. per square foot is about the maximum amount consistent with good work, and this figure is in fair agreement with most practice of to-day, though I have operated furnaces burning over 300 lb. per square foot with excellent results in fuel economy for the given conditions. On the other hand, the large-hearth furnaces with which very economical results have been reached in very recent years are only burning about 40,000 lb. of coke per hour in a 17½-ft. hearth, which is less than 200 lb. per square foot.

It has seemed to me that this basis of comparison was not altogether a correct one. I have endeavored to show in the earlier articles that the real combustion space of the furnace was not a single plane at the tuyeres, but that combustion was going on throughout the bosh, that is, from the tuyere plane to the top of the bosh, and in order to obtain truly comparative figures we would rather use the combustion per cubic foot of this space than per square foot of hearth area. On that basis the large-hearth furnaces are really as hard driven as any, for two reasons: First, while the hearth is very much larger than that of other furnaces with the same height and bosh diameter, by this method of figuring this change affects only the smaller diameter of the frustum of an (inverted) cone whose base is the bosh diameter, so that the percentage of change in its volume produced by this increase in its smaller diameter is less than half that produced in the smaller area itself. Second, the wide-hearth furnace has been accompanied by a lowering of the top of the bosh so that its vertical height is decidedly smaller, and this reduces the volume of this zone of the furnace as much as the widening of the hearth increases it.

It is an unfortunate fact that we have no figures for coke consumption per cubic foot of bosh space, and this unit of measure can therefore only be introduced into general use after a considerable campaign to replace the older but less accurate unit.

Concerning the results of the true rate of combustion upon fuel economy we know much less than we should, but some of the factors which affect it may be pointed out. The first of these is the velocity of the combustion of coke in a blast initially air, but burning progressively to CO and nitrogen. A simple calculation shows that the blast can be but a few seconds in passing from the tuyeres to the top of the bosh. The volume of air blown into the modern furnace is about sufficient to fill it twice a minute if the furnace were empty and the air under atmospheric conditions. As a matter of fact the air is increased in volume between three and four times by heating, and this volume is reduced by the compression under which it enters the furnace, this decreasing, of course, as it rises, so that its average pressure is one and a half times atmospheric, while its absolute temperature at the top of the bosh is six or seven times atmospheric, and the average something

like four times atmospheric, hence its actual volume is nearly three times that under atmospheric conditions. This would mean that the furnace, if empty of solid and liquid matter, would be filled six times per minute. But we have seen that if it were filled with uniform spheres the total voids would only be about 25 per cent of the total, and with very irregular material, including much fine, continually settling and thereby reduced to minimum volume, the voids are probably not over a half of this, perhaps much less, so that the voids are probably only about an eighth of the total contents of the furnace. This indicates that the actual gas volume is sufficient to fill the voids at least forty-eight times per minute, so that in about one second the blast which enters at the bottom of the furnace passes through it and is discharged as gas at the top.

Now taking the height from the tuyeres to the top of the bosh as one-eighth or even one-sixth of the total height of the furnace we see that less than one-sixth of a second is available for the complete combustion of the oxygen of the air to CO. Such a velocity makes it impossible that combustion should go on in the interior cells of the coke because it is impossible that the air should penetrate a solid (though porous) structure and make its exit in that time; therefore combustion must proceed only upon the surface of the coke. This is not unlimited, and as we know that an appreciable interval of time is necessary for the complete combustion of air it becomes evident that there is a limit beyond which we cannot drive the furnace and have the combustion completed in the proper zone.

This means that for still faster driving more volume would be necessary to complete the combustion, and, therefore, that this would extend to a higher level in the furnace. All our experience in operation, and all of the chemical and thermal theories set forth in earlier chapters tend to the conclusion that the best work can only be done by keeping the zone of fusion as low as possible. It is impossible to go over all the reasoning which leads to these conclusions here; it is a fact based primarily on experience, and one of the best proofs is that the remarkable work of the wide-hearth furnaces has been built upon and around the principle of keeping the zone fusion as low as possible, and the economy which has been obtained in furnaces in which a low bosh is one of the outstanding features, creates a strong presumption that the lowering of the zone of combustion is at least an important factor in the very economical results obtained.

When furnaces are overblown it is a quite general impression, and I believe an entirely correct one, that the upper zone of combustion rises, in accordance with the above reasoning, and this is accompanied by an increase in fuel consumption. In fact, it must be evident that if the fuel consumption be controlled by the quantity of high temperature heat available, anything which tends to dissipate this limited supply of heat over a wider zone must militate against its concentration, and therefore against fuel economy.

The same reasoning which applies to combustion applies to other reactions which must go on. The reduction of the ore is essentially a task which demands time for its completion in the maximum degree possible in each zone before descending into the next, and as this is the essential condition for the maximum possible oxidation of the gases, on which, as we have seen, the total heat development depends, a sufficient allowance of time for the completest possible reduction of the ore in each zone is an indispensable condition for maximum economy. If the ore descends so rapidly as to reach the hearth without the completest possible reduction, the effect is of the same general kind, but of a much higher

order of intensity. We have in such a case the conditions which led to low fuel economy with the wet ore in the charcoal furnace, described in the article on thermal principles.

So it is with all the other reactions; the decarbonization of the limestone, the complete union of the flux with the impurities of the charge, etc. If sufficient time be not allowed for these we shall pay for it by expending more heat than is absolutely necessary upon bringing about the necessary conditions. On the other hand, we shall see later in the present article that there are heat losses of vast importance which are irrespective of the rate of driving. The furnace is constantly undergoing a loss by radiation and cooling water of some 15 or 20 per cent of its heat, especially of that in the hearth; this is 15 per cent of the total developed when the furnace is running at full speed, which is a convenient measure.

But if the furnace stops, the loss continues at the same rate per hour as long as the zones of the furnace remain at the temperature which they have in operation, so that if the furnace were to be run at 15 per cent of its normal rate we should supply just enough heat to make up for the losses without supplying any for the production of iron; if we ran at 30 per cent of the normal full rate we should, on this basis, lose 50 per cent of the heat produced, and the fuel consumption would accordingly be nearly twice what it is at the normal full rate. If we drive at 45 per cent we lose one-third on the same basis, and so on. The figures used are not intended to be exact, though they are approximate to the best of our knowledge.

This line of reasoning shows that we must not allow any more time for combustion, reduction, etc., than is necessary for those operations. We are not at liberty to increase the economy of the furnace indefinitely by slowing down to obtain more complete reactions, because the purely physical radiation and reduction losses begin to assume an increasingly menacing proportion the slower we run. Obviously, then, if we make some loss by allowing a slightly insufficient time for complete reduction, we may offset it by cutting down the radiation losses in a greater degree. If we were considering only fuel economy, our effort should be to run under the conditions which would make the sum of these two losses the minimum. But we shall see when treating of commercial considerations this is only one factor and sometimes by no means the greatest in the solution of the commercial questions involved, and therefore it would be useless to attempt a solution of the purely technical question involved on so theoretical a basis.

FIG. 1—THEORETICAL AND ACTUAL HORSEPOWERS REQUIRED TO COMPRESS 1000 CUBIC FEET PER MINUTE OF FREE AIR (14.7 LB.) TO DIFFERENT PRESSURES

FIG. 2—HORSEPOWER-HOURS PER TON OF IRON PRODUCED REQUIRED TO BLOW FURNACES WITH DIFFERENT BLAST PRESSURES

The Effect on Power Required for Blowing

This is a subject of the utmost importance from two points of view: first, that of the first cost of the blowing plant; second, that of the consumption of gas required to operate it. The time was when the gas was considered of no use or value, but that time is now long gone by, and it is well understood that the gas represents roughly one-half the value of the fuel, in the best and most convenient form, and in modern plants it is applied to the production of power for uses outside the blast furnace and is an asset of great value. Therefore, it is desirable to use as little of it as possible for the blowing of the furnace itself, since power so spent is a necessary evil and nothing else.

The power required for the compression of a given volume of air to a given pressure varies with the type of apparatus used whether steam engine, gas engine or turbo blower.

More data are available in the case of the steam engine, and I have therefore used it for developing the facts in the following discussion. The lower curve of Fig. 1 shows the theoretical power required to compress adiabatically 1000 cu. ft. of air per minute from atmospheric pressure (14.7 lb. abs.) to different pressures. The upper curve shows the actual indicated power required in the steam cylinders of a blowing engine to compress it to the same pressures with normal assumptions based on practice as to the efficiency of the blowing cylinders and the friction of the engine. By assuming now a figure for the amount of air to burn a pound of coke and the amount of coke consumed per ton of iron we obviously can calculate the horsepower-hours per ton of iron with different blast pressures. The curve of Fig. 2 gives these figures based on normal assumptions for Lake ore practice. But in order to obtain the information that we really need we must go a step further and find the horsepower-hours per ton required with different rates of blowing in a given furnace.

By assuming that the results of the blast pressure chart given in the article on mechanical principles are correct, and combining its results with those just given we may obtain a very fair idea of the horsepower-hours required per ton of iron produced at different rates of blowing. Fig. 3 gives the results of such calculations for a 22.5 x 90-ft. furnace.

It will be seen that the total horsepower required for blowing rises very rapidly, and that the horsepower per ton of product rises at a rate almost exactly proportional to the rate of driving; at 350 tons per day 75 hp.-hr. per ton are required, and at 650 tons 150 hp.-hr. This increase of 75 hp.-hr. per ton represents a real loss.

even if the gas be worth nothing, for the fixed charges on the investment and the operating labor to burn it and utilize the resulting steam are important, however much or little the gas may be worth. Leaving a more extended discussion of these values to a later chapter, we may note that the sum of fixed charges and labor is seldom less than 0.25 cent per horsepower-hour, and therefore the difference in power cost at these two rates of driving is nearly 20 cents per ton.

It may well be reiterated that these are not absolute figures, and that they may vary considerably from the actual figures in a specific case, but that they are based throughout on assumptions in substantial agreement with facts, and it is believed they represent very well the relative power requirements under the given conditions.

Similar curves worked out for smaller furnaces show the same characteristics with so little difference, except in absolute values, that they need not be reproduced here.

The results will be shown in dealing with commercial considerations.

Effect on Flue Dust Loss

This is frequently the really controlling consideration as to the rate of driving in fine ore practice.

A. N. Diehl in presenting his paper "Data Pertaining to Gas Cleaning" (A. I. M. E., Trans. Vol. L, page 3), stated verbally as the result of careful investigation that the surface of the stock in a modern furnace was in a continual state of "teeter," particles rising in the gas current and falling back continually; under these conditions some of the finer particles must be regularly carried over by the gas, and we know they are. The lifting power of a current on an individual particle increases as the square of the velocity, hence the number of such particles which would be within the lifting power of a slightly increased gas current is very great, and as a result such an increase would quickly lead to a prohibitive flue dust loss; in other words, the difference in rate of driving between an insignificant and a prohibitive flue dust loss is a very small one, and the maximum permissible rate is found in this narrow range.

With the rapid progress being made in sintering flue dust it seems not impossible that our ideas on the subject of this limitation may experience a considerable change in the near future. The harmful effect of fine ore in the furnace has been explained earlier, and is coming more and more to be admitted, the uselessness if not absolute harmfulness of fine coke is well known; if we can transform these into a highly desirable furnace material without undue expense we may find that

the cheapest course is to blow out of the furnace an increased percentage of the objectionable fine materials, put them into a desirable condition and change them back again.

Where lumpy or plastic materials are used the flue dust loss is smaller in proportion to the smaller total quantity of fines present, and this is generally so small that flue dust ceases to be an important fact in the rate of driving under such conditions.

In actual practice we find by experience the rate of driving which suits the general conditions best, and that we regard as the normal which we desire to maintain.

Spontaneous Increase of Rate of Driving

There often arise conditions under which the maintenance of the best rate of driving is no longer possible. The furnace will sometimes start off and drive at a vastly increased rate without any change in the amount of blast having been made. For many years I did not know the reason for this phenomenon. It was first pointed out to me by A. J. Boynton of Lorain, that this condition arises from the fact that the rate of coke loss by solution or, more accurately, the percentage of the coke dissolved in the upper portion of the furnace, suddenly increases from some change in conditions, perhaps the distribution of the stock or a change in the tightness of the charge, producing a corresponding change in the equilibrium of CO and CO₂, with the result that more of the latter is formed at some zone, and this then dissolves more carbon from the coke in order to restore the equilibrium.

Another cause for such change, probably the most frequent one, is increased solubility of the coke due to a difference in oven practice, coal used, structure, or the like, or to a change in the fineness of the ore or its tendency to run down through the charge.

If a furnace working on hard ore were to change from a 10 per cent solution loss to the 22½ per cent solution loss which may occur with all fine ore, it would produce an increased rate in driving of about 15 per cent, and changes as great or even greater than this do at times occur.

The effect of such an automatic increase in driving is usually very objectionable for two reasons: First, it reduces proportionately the time permitted for the complete reduction of the ore; second, and much more important, it corresponds to a reduction of fuel in the hearth and a reduction of hearth heat available, exactly proportional to the increase in the rate of driving. Since, the quantity of blast being constant, the coke to satisfy it must be constant, and if each charge delivers less coke to the hearth proportionately more coke charges are consumed; that is, the rate of driving is increased.

As a result a furnace generally runs off cold in consequence of such a spell unless measures be taken to prevent it. The principal measures available are first, to increase the blast heat if possible so that it may make up the deficiency caused by the extra solution loss; second, to slow down the blowing engines so as to prevent the rapid driving even though the solution loss cannot be checked. If this does not result in reducing the driving to a rate proportional to the blast blown it is then necessary to reduce the burden to make up for the hearth heat lost. As a general thing a reduction in the rate of driving is usually accompanied, temporarily at least, by increased heat in the hearth due, presumably, to the more complete preparation of the stock before its entrance therein, and slowing down the blowing engines is, therefore, the proper procedure if the abnormal rate of driving be long continued.

FIG. 3. BLAST PRESSURE, BLOWING POWER AND HORSEPOWER PER TON REQUIRED AT DIFFERENT RATES OF PRODUCTION WITH A FURNACE 22.5 X 90 FEET

Reduced Driving Caused by Furnace Becoming "Too Hot"

We sometimes encounter a phenomenon the exact opposite of that last described. The furnace becomes very hot, the silicon in the iron rises, the actual temperature of the slag and iron rise visibly, and presently the furnace slows down, "won't take the wind," the blast pressure rises decidedly, the rate of driving falls off, and presently the furnace begins to hang and refuses to settle without slacking the blast.

We do not know absolutely the cause of this condition, but as the exact opposite is caused by a sudden increase in solution loss, it is reasonable to suppose that this is caused by a sudden diminution of solution loss bringing an excess of carbon into the hearth.

This would cause the rate of driving to be slowed down in proportion to the increase in carbon delivered to the tuyere zone per unit of time. Increased hearth heat would be developed in the same proportion, part of this would expend itself in reducing more silicon, and the rest would pass out the top of the bosh and carry the pasty zone to a greater height, thereby causing the pressure to rise, and this co-operating with the greater depth of pasty zone would cause a decided increase in the lifting action on the charge column with sticking and hanging as necessary consequences. These are so exactly the results which we see in practice under these conditions that it seems safe to assume that the cause suggested is the true one.

A further confirmation is to be found in the serious after-effect of these conditions which is only too likely to be the scaffolding of the furnace, which is what we should expect from the rise of the pasty zone due to the excess of hearth heat.

After this was written I obtained extraordinary confirmation of its correctness from a chart of pressures at different heights during a "hot stick" furnished me through the kindness of Mr. John N. Reese and his assistant, R. C. Wallace, shown at Fig. 4.

It will be seen that the pressure drop in the bosh and that in shaft are about uniform, whereas in the zone just above the top of the bosh the pressure drop is 6 lb. in 9 ft. where it should be about $1\frac{1}{2}$ lb., so accounting for nearly all the excess pressure in the exact location where we should expect the abnormal sticky zone to be. It is interesting to note that this occurs in the straight section at the top of the bosh; if this were

absent and the upwardly covering shaft started directly on top of the bosh it is easy to believe that the sticking would be much worse.

Granting that the cause of this action has been found, what is the remedy? Obviously it is to dissipate the excess heat before it can carry the pasty zone much above the normal level and so prevent the formation at that level of a scaffold due to the adherence of chilled pasty material to the walls when normal temperatures are restored.

This can best be done by "following up" with more blast if the power is at hand to deliver it, for the same reason that we slow down when the furnace is running away. This tends to dissipate the excess heat, or rather to give it less time for action and also to keep the charge in rapid motion and so prevent scaffolding. Unfortunately, the high pressure which accompanies this condition not infrequently limits the quality of wind which can be delivered at the very time we need it most.

In such a case we have no recourse but to cool the furnace off by lowering the temperature of blast to the point required to restore normal conditions. Of course, if the furnace shows a tendency to continue these conditions indefinitely the remedy is an easy and agreeable one, we simply add enough more burden to take care of the excess hearth heat and restore the normal blast temperature, but at the beginning of such a condition a change cannot be brought through quickly enough to prevent bad consequences, so the other remedies must be applied first in any event, for they reach the seat of the trouble instantly.

The Effect on Life of Lining

It was at one time believed that any rate of driving in excess of a very moderate figure must necessarily result in reducing the length of life of the lining and increasing almost prohibitively the expense and loss of time for relining.

We know now that this is not generally true and that where practice has been good the greatest tonnage per lining is made on steady and uniform but fairly rapid driving.

As a matter of fact, rate of driving is only one, and by no means the most important factor in the life of lining.

The really controlling feature in life of linings is stock distribution. If that be correct we shall be able to drive faster and still have the lining last many times longer than it does with poor distribution; channelling due to the concentration of the lumps on one side of the furnace has destroyed countless linings in a few weeks, but even when this is absent there are frequently conditions due to distribution which destroy a lining quickly. In the next article I shall describe a case in my own experience in which a change of distribution gave a life of lining three times as long as before.

Slow driving may be almost as destructive of linings as excessive driving, for the movement of the charge becomes so slow that the whole of the furnaces is not kept in action, a portion of the charge ceases to descend and by long contact adheres to the wall and a scaffold is formed; this causes irregular work and channelling which quickly cuts the lining out, or else the scaffold eventually falls off and brings a quantity of brick with it, this starts a failure of the lining and its end soon comes.

There are other conditions than wear which destroy linings; they disintegrate behind the glazed face which forms on the bricks sometimes in a comparatively short period, three or four years or even less. A lining is just as effectively destroyed by this action as if worn

FIG. 4—CURVE OF PRESSURE DROP

out, and therefore might better have been worn out so as to obtain maximum production from it.

Speaking broadly then, we may say that while the rate of driving is one factor in the life of linings, it is such a small one, with proper conditions in other respects, that we may disregard lining cost in determining the best rate of driving.

From all that has been said as to changes in the height of the pasty zone, the danger of scaffolding they cause, etc., we may see some of the reasons for one of the best established facts of practice, that the best work can only be done over a long period by determining the best rate of driving and adhering to it rigidly except when corrective measures are needed temporarily. The furnaces which have in the long run made the best showing technically and have made the most money for their owners are run on that principle.

The Metallurgy of the Rarer Metals*

BY JOSEPH W. RICHARDS

There are many metals which may be called "the rarer metals." Among them the most interesting by far, to the metallurgist and to the economist, are those metals whose compounds are relatively cheap but which command a high price because of the difficulty of their reduction. These are the metals whose market price may at some time be reduced one-half, three-quarters, perhaps nine-tenths, by improved methods of reduction, and the discussion of how this might be accomplished and to what uses these metals at such low prices might be put, is interesting to the border of fascination.

If this article were being written thirty years ago, aluminium would be one of the metals to be discussed. It is now out of that class, but in 1886 it was one of the rarer metals, selling at \$10 per pound, although its ores were "as common as dirt." At that time you could buy a ton of bauxite ore containing 6/10 ton of alumina or 3/10 ton of aluminium, for \$5, while the 3/10 ton of aluminium was being sold for \$3,000, at wholesale. Or, eliminating the purely chemical work, 6/10 ton of chemically purified alumina could then have been bought for \$50, while the aluminium it contained was worth on the market sixty times that amount. Such were the metallurgical conditions in the aluminium industry thirty years ago, and so attractive were they to experimenters and inventors that the genius of the profession expended its best talents on the problem, with the result, in less than ten years, of reducing the market price to less than one-tenth its former figure.

The silicon industry furnishes another example in point. Silica is the most abundant and cheapest material in nature, yet silicon was selling in 1900 as a chemical curiosity at over \$100 an ounce. Imagine the stirring up which my metallurgical wits received, when in 1902, Mr. Tone, at Niagara Falls, showed me a barrel full, 100 lb. perhaps, of silicon made in his electric furnace, and asked me what uses it could be put to. At the present time, 10 cents per pound is a good market price for silicon, which is often sold by the carload.

It is such seeming fairy tales as these which constitute the fascination of those metals which are abundant in nature but whose high cost rests on the difficult and costly methods of reduction employed. Such opportunities exist, for our rising generation of chemists and metallurgists to make themselves famous and, incidentally, rich—but they will find their fame more of a reward than their riches.

Among the metals at present of high price, but which by improved metallurgical processes might be made very

cheaply, are beryllium, boron, magnesium, calcium, strontium, zirconium, molybdenum, barium, titanium, chromium and cerium (mixed metals of the cerium group).

Beryllium

Commencing with one of the light, alkaline-earth metals, its ore is not as rare as is ordinarily supposed. Most non-mineralogists link it with beryl, and think of the latter as a very pretty and very expensive gem—the emerald. But the emerald is only the clear green or aquamarine stone, while massive beryl, looking like massive green quartz, is much more common, and is even abundant in some localities. The beryl crystals of Acworth, N. H., are sometimes as large as a barrel, and the massive beryl at this locality is quarried like feldspar. Its composition is

SiO ₂	67.0 per cent
Al ₂ O ₃	19.0 per cent
BeO	14.0 per cent

It is difficult to say what the price of this material would be if it was desired by the ton, but it should not be expensive. When chemically treated, both the Al₂O₃ and the BeO which it contains could be separately obtained.

Up to the present, no one has succeeded in isolating the metal except by reducing a halide salt of beryllium by potassium or sodium (Bussy, Wöhler, Debray, Menier, Reynolds, Nilson and Petterson, Kruss and Morah) or by electrolysis of double chloride, bromide, or fluoride of beryllium and sodium or ammonium (Borchers, Warren, Lebeau, Liebmann).

These methods are tedious and costly for two reasons: first, they require the conversion of the beryllium into an anhydrous halide salt, which is a difficult chemical operation, and, second, the electrolysis sets free the halogen, which is very destructive of electrodes and apparatus. It is not to be expected that beryllium can be made cheaply until someone masters the direct electrolysis of the oxide, dissolved or suspended in a more stable melted salt. This is by no means an impossibility; a similar solution was found for the aluminium problem, and systematic, determined search would in all probability find the answer for beryllium. In such a case, the cost of the metal would depend only on the cost of beryllium oxide, being probably not more than 20 cents per pound plus the cost of the oxide. Since BeO is only 36 per cent Be, it would require 3 lb. of oxide to give one of metal; if the oxide cost 10 cents per pound, the total cost of the metal should not exceed 50 cents, by such a supposition process. Dealers in rare chemicals will charge you, at present, \$300 per ounce for a specimen of it.

Lebeau has produced beryllium bronzes by reducing directly, in the electric furnace, a mixture of beryllium oxide, copper oxide and carbon; 0.5 per cent of beryllium makes copper hard and sonorous; 1.5 per cent makes it yellow, and 5 per cent makes a fine golden yellow bronze.

Beryllium, like any other rare metal must find uses which justify its cost. Being white, malleable and unchanged in air, its specific gravity, 1.64, would make it particularly useful for objects where great lightness and permanence in air is the first consideration and cost secondary. So far we practically know nothing about its tensile strength or rigidity, about how it might be strengthened or stiffened by small additions of magnesium or aluminium or even of zinc, or copper, or manganese, or some other metal. We do not yet know the mechanical properties of its fine bronzes, except that they are somewhat similar to aluminium bronze, but in what respects they might be superior or perhaps unique is unknown. Finally the metal may

*A paper read at the Cleveland meeting of the American Institute of Chemical Engineers on June 14, 1916.

easily possess special properties, now unknown, which may render it particularly useful for some specific purpose. Its specific heat, for instance, is the highest of any useful metal, and its latent heat of fusion must be abnormally high, possibly 300 calories, and its latent heat of vaporization probably higher than that of any known element except carbon or boron. Such characteristics might give it special uses in electrical instruments, or for physical apparatus, where its cost would not exclude its use. Altogether, beryllium is a metal which will well repay extended metallurgical research and minute physical and chemical study of its many unique properties.

Magnesium

The metallurgist has been coquetting with magnesium for half a century, and has, as yet, not made a fraction of the progress which he should have made. We can get its oxide cheaply and in abundance, its salts are not very difficult to prepare, we know their properties to a considerable extent, we know almost all the properties of the metal which bear on its isolation, and yet the industry lags and halts as if there were no such thing as modern metallurgy. To prepare by tedious methods the anhydrous double chloride, and then to electrolyze it about as Matthiessen did fifty years ago, is nearly all that can be said with certainty about its present metallurgy. At any rate, using magnesium oxide costing a few cents per pound, the metal sells for about as many dollars per pound, and yet there is a great scarcity of the metal.

Dr. W. M. Grosvenor, in a recent paper before the American Electrochemical Society, summarizes the present methods of production and the uses of the metal. Happily he also suggests the great field open for improvement, especially for radically new metallurgical methods of production. With magnesium in its salts costing less than 8 cents per pound, he places the actual cost of the metal at \$1 per pound, leaving over 90 cents per pound for the cost of its extraction. "Brethren, these things ought not so to be." Speaking with the enthusiasm born of past achievements in electrometallurgy, along entirely analogous lines, a modern, up-to-date attack on this problem ought to result in producing magnesium at 25 cents per pound.

The point of attack should be undoubtedly to reduce the oxide directly. The halogen salts are hygroscopic, and the halogen is destructive of the reducing apparatus. It is almost certain that proper research will enable the electrometallurgist to feed MgO directly into an electrolytic bath of fused salts and take magnesium or magnesium alloy from it. The pure metal will float on almost any fused salt, but its alloy with heavier metals may be made such as to sink, and many of its alloys have immediate useful applications.

Dr. Grosvenor makes suggestive remarks about the reduction of magnesia by carbon. If the boiling point is only 1200 deg. C., then a process of reduction similar to that of zinc oxide might be practicable if we could (1) find a retort material which will stand the temperature required (1800 deg. to 2000 deg. C.), and (2) condense the vapors without contact with air. Fortunately, magnesium does not form carbide at high temperatures, so that its reduction is simpler by that much. Dr. Grosvenor speaks of a chemical process which will use cheap raw material, a moderate amount of fuel, and give a fair efficiency of reduction. With all expenses added, he estimates a cost not over 35 cents per pound. This may be true, but whether it materializes or not, he and his colleagues have the right vision of the possibilities, I may even call them the probabilities, of this field; they are truly "absolutely fascinating."

While the world-war lasts, with its enormous demand

for magnesium for military purposes, the price will remain in the dollars per pound. But experience in this line is being rapidly accumulated, and improvements are undoubtedly rapidly succeeding each other, although keen competition is keeping them secret as far as possible. After the war's close, with normal industrial conditions reappearing, magnesium will undoubtedly sell at a price which will take it out of the class of the rarer metals and put it among the common ones. As the price goes down its industrial uses will increase in a geometric proportion, and instead of production being expressed in thousands of pounds per year it will reach thousands of tons. This will be another of the by-products of the great war's stimulus to metallurgical industry.

The possibilities held out to the metal industry by reasonably cheap magnesium are extremely interesting. The stiffening of magnesium to produce strong alloys with specific gravity not over 2 has not been properly studied. It is quite possible that alloys analogous to *duralumin* may be discovered, as strong as soft steel and only 30 per cent of its weight, which will find extensive use in aeroplanes and dirigibles. Such alloys may also largely displace aluminium alloys, which are used by thousands of tons annually in the automobile industry, with a saving of one-third in weight, which will compensate for a higher first cost. The metallurgical uses of magnesium will also be greatly extended by its lower price, such as for deoxidizing brass, bronze, nickel, monel metal, since it is a much stronger deoxidizer than aluminium. In fact, aluminium has blazed the way into numerous uses for which magnesium, as soon as it becomes cheaper, will compete and replace its older sister. With supplies of magnesium ore as plentiful as those of aluminium ore, and the metallurgist awake to his responsibilities and producing the metal cheaply, there will inevitably be a large future for magnesium as one of the common metals of every-day life.

Calcium, Strontium, Barium

These are a trio of highly interesting elements, common enough in nature, but all scarce and of high price because of the metallurgist's lack of efficient and cheap methods of reduction. With burnt lime, CaO, one of the cheapest of common materials, strontium sulphate, a mineral found in considerable abundance, and barium sulphate, so common, as heavy-spar, that it is used as an adulterant for some cheap paints, the metallurgist is again faced with the demand for cheap methods of reduction. And yet, although calcium is sold at a few dollars a pound, strontium and barium cost several dollars per ounce. Here is a twofold need: first, cheap production; second, a thorough study of these metals to find out their specific properties and their particular uses. Which should be undertaken first is an interesting topic for discussion. Historically, the metallurgist has usually produced the metal first and then studied its properties and possibilities; at present, with these metals already at hand, metallurgical activity might be greatly stimulated by extensive studies of the properties, alloys, and chemical uses of these elements. Our present information in this direction is fragmentary and partly unreliable as far as it goes. A Carnegie Research scholar, or even the Bureau of Standards, by disclosing to us some of the unknown properties of these elements, might stimulate the experimenter to renewed efforts to find cheaper methods of reduction.

Calcium, at the present time, is the best known of these three elements. The method of electrolyzing its fused chloride and lifting the metal away from the surface, as an irregular stick, has been fairly successful, and since the chloride is not difficult to dehydrate, the whole operation is not very expensive. Calcium is there-

fore, at present, perhaps a semi-rare metal, which could be produced much cheaper even by present methods if made on a large scale to fill a large demand. The method of production is easily susceptible of minor improvements, and the chlorine is a valuable by-product to the manufacture. The principal hitch at present is in finding the uses for a large production of calcium. Here is where extensive study of the properties and possible uses of calcium would greatly stimulate the metallurgical industry. With specific gravity of 1.85, its possible alloys with other light metals should be exhaustively studied; quite possibly some of them are strong, resistant to air and water, perhaps even to acids. Calcium tarnishes easily in the air, and magnesium also, but it is quite possible that some alloy of the two does not tarnish, and may have valuable mechanical properties. Another large possible use is as a chemical purifying agent in melting and casting metals. Calcium-silicon-aluminum alloy has already found application as a deoxidizing agent in steel, because while aluminum oxide and silicon oxide and their combination with each other are infusible at steel-melting temperature, and therefore are eliminated slowly from the metal, calcium oxide forms with these an easily fusible slag, which easily rises out of the molten metal. It is quite possible that a small addition of metallic calcium may in a similar manner reduce the amount of sulphur and phosphorus in steel, because it is either as calcium sulphide or calcium phosphate that these elements are eliminated in refining steel. Other metals and alloys whose properties are damaged by sulphur or phosphorus may be similarly refined or improved. The alloys of calcium with copper, tin, bronze, brass, monel metal, and other commercial alloys have not been studied; until they are, no one knows how many useful mixtures may exist with particular properties of industrial value. The question of adding calcium to the light stiff aluminium alloys, for instance, is worthy of attention, but has not been touched.

Strontium is a silvery-white, very soft metal, with properties similar to calcium, density 2.54. Its ores cannot be called rare minerals, and it is a rare metal, therefore, only because of the difficulty of its isolation. It is chemically very active, and electrochemically extremely hard to manage. It has about the same specific gravity as its fused salts, so that it neither rises nor sinks in any of them quickly; it seems also to redissolve in its melted salts with great velocity, so that very high current density is required to obtain any metal at all. Its surface tension appears to be abnormally high, so that it separates out in more or less minute globules which are highly indisposed to running together into one mass. What an attractive subject this forms to the electrochemist who really wants to meet difficulties and taste the joys of overcoming them. And then one may well ask: To what purpose? Here, again, we do not know, but we can feel confident that in the innumerable list of possible combinations of metals strontium might have properties different from any other element, which would lead to its employment on a large scale. These are all questions of the future which form the undiscovered country open to the investigator and chemical pioneer. We may well thank our stars that the world of science still holds unexplored areas to tempt the adventurous investigator and to reward the *Wanderlust* of the metallurgical pioneer.

Barium is common in its compounds and almost unknown in itself. Under electrolytic conditions where calcium comes out *en masse*, and strontium separates as small globules, barium is obtained only as a fine powder. Its density is 3.75, but its salts are heavier than the corresponding strontium and calcium salts, so that the

fine powder may sink or swim, largely according to the temperature. And yet the fused barium salts are very decent and manageable salts, easily obtained anhydrous and melting cleanly. Their electrolysis, however, is nearly the most difficult task that the electrometallurgist can take up. But it should be taken up and mastered, because a metal so common in its compounds could be obtained in large quantities if uses for it were developed, and if our modern electrometallurgists are worthy successors of Faraday, Bunsen and Castner, they should vigorously attack the problem of its cheap extraction. Even if their end was not reached, they would be whetting their metallurgical wits upon the finest of chemical whetstones, and their experiences would be of value to themselves as well as to other lines of electrometallurgy.

Boron

As an intermediate element, semi-metal, cheap and abundant in its compounds, yet almost unknown as an element, boron is very interesting. Although quoted at several dollars an ounce, yet there are possibilities of it being made for x cents per pound, where x may be anything over 25. It is only the prophetic prescience of the enthusiastic metallurgist, however, that can discern this goal in the distant future.

Boron occurs in nature as its oxide, sassolite, containing 31 per cent of boron; as borax, containing 11.5 per cent of boron, and as colemanite, containing 18.9 per cent of the metal. These sources are comparatively abundant, the oxide being found in volcanic districts, borax near dried-up lakes, and colemanite (calcium borate) being literally a waste product of the borax mining for which no use has yet developed.

Gay-Lussac and Thenard, Wöhler and Sainte-Claire Deville reduced the oxide by potassium or sodium, other chemists by phosphorus, magnesium, aluminium and calcium, while Duncan reduced boron chloride gas by hydrogen. Chemically, its reduction does not appear to be of extraordinary difficulty. Electrochemically, Davy electrolyzed fused boracic acid, Gores potassium borofluoride, and Faraday fused borax. All describe having isolated boron. Quite recently, Weintraub has decomposed boron chloride by hydrogen in a high-tension arc, and obtained purer boron and in larger quantity than any previous investigator. His classical paper is in the *Transactions of the American Electrochemical Society* (1909) 16, 165.

The properties of the pure boron obtained by Dr. Weintraub are exceedingly interesting. Its fusing point is extremely high, between 2000 deg. and 2500 deg. C.; it was fused in a boron nitride crucible under the pressure of its own vapor. Its boiling point is near to its fusing point; it has considerable vapor tension as low as 1600 deg. C. It has a conchoidal fracture, and is nearly as hard as the diamond. At room temperature it is electrically almost a non-conductor, but at 500 deg. C. its conductivity has increased 2,000,000 times; at 1000 deg. C. its conductivity is of the order of that of the metals. Applying moderate voltages to a cold piece, it soon warms up and makes itself a good conductor. Such extraordinary properties suggest its use for many interesting electrical contrivances, which are enumerated by Dr. Weintraub.

Other uses of boron, which have not yet been thoroughly investigated, are in the formation of boron steels and boronized copper. The former were investigated by Guillet, in France, with irregular results; in some respects, at times, the effects were similar to that of vanadium in the famous vanadium steels, at other times the results were different. The uncertainty may have been due to irregular composition of the ferro-boron alloy used. A great amount of investigation should be

done on this line, first in making a reliable quality of ferro-boron, and second in using it systematically in various qualities of steel. The question of boronized copper is in a still greater state of uncertainty. Boron or even boron sub-oxide (B_2O_3 or, perhaps, boron saturated with B_2O_3) added to melted copper enables a perfect copper casting to be obtained of practically 100 per cent electrical conductivity; a trade product sold as boronized copper has similar effects in producing sound copper castings. These results are only the beginning of an extensive field of investigation of the effects of small amounts of boron on metals and metallic alloys. They will certainly lead to important metallurgical discoveries and improvements.

In metals and alloys boron can act chemically as a purifying or refining agent to remove oxygen, nitrogen, and perhaps sulphur, phosphorus, and dissolved oxides, while in larger amount it acts metallurgically as an alloying element. In the latter respect it forms true alloys, such as the ferro-boron alloy, which is an article of commerce. The possibilities of extensive use in molten metals and alloys are great, but mainly dependent upon systematic metallurgical research in properly equipped laboratories.

The production of the metal and its alloys also needs expert attention. For use in steel, a good uniform quality of ferro-boron is needed, and the manufacture of this in satisfactory uniform quality has not yet been mastered. Some years ago, the Pacific Coast Borax Company offered a prize of \$500, to be awarded by the American Electrochemical Society, for a practical electric furnace method of producing ferro-boron directly from calcium borate (colemanite), a waste product of the borax mines. A few years later the prize money was returned by the society to the company as not having been earned, although several attempts were made at it. For use in copper, brass and bronze, a cupro-boron alloy answers as well as having pure boron. One method of making this is being tried, and the product is giving some very satisfactory results. Improved and more certain means of getting boron into copper are needed, and could probably be found by a moderate amount of careful investigation. As for pure boron, and the fascinating possibilities dependent on its remarkable properties, Dr. Weintraub's method makes the product, but at considerable expense, and a cheaper, easier method is a great desideratum. If such is found, boron will certainly occupy an important place among the useful metals.

Chromium

This element is also common and abundant in nature, and rare and expensive as a metal. Chromite, containing 34 per cent of chromium, costs normally \$20 to \$25 per ton, while the ferro-chromium alloy produced from it sells at \$100 to \$550 per ton, according to the per cent of chromium and carbon contained. But pure chromium, carbon-free, is produced only by reduction of chromium oxide by aluminium, and commands 75 cents per pound. The use of chromium in steel is rapidly extending to all varieties of extra hard and high-speed steel, but the use of pure chromium is limited by the high cost of its production and our lack of knowledge of how to handle it and of its possible useful effects. For example, chromium electroplating is white and durable, and for many purposes may be superior to nickel and almost equal to platinum plating, but the technique of always getting perfect plating has not been satisfactorily mastered. Cobalt-chromium alloys have been made which have some of the remarkable properties and uses of high-speed tool steel (stellite alloy of Mr. Haines). This is an excellent example of totally unexpected and valuable physical properties being discovered

by systematic investigation. These alloys, however, must be made from pure chromium and not from ferro-alloy. How many other remarkable alloys yet remain to be discovered by patient and intelligent investigation no one knows or can even guess.

As for the methods of reduction, ferro-chromium alloy carrying high carbon (6-8 per cent) is produced quite cheaply in crucibles, cupola furnaces, blast furnaces, or electric furnaces. Low-carbon ferro-chromium commands three to five times as high a price, because of the difficulty of decarbonizing the raw product. It is very much to be hoped that tests will be made in the electric shaft furnace to see if it is not possible to produce directly from the ore a low-carbon product. The thing has been done in the case of pig iron, producing a low-carbon product which is called pig steel; there is no inherent impossibility in similarly mastering the conditions for producing directly the low-carbon ferro-chromium. The present prices of the two products, \$100 and \$500 per ton respectively, would warrant great efforts in that direction.

Similarly, chromium is not a difficult metal to reduce to the metallic state, but it is a difficult question to find the proper flux and to keep carbon out of it. Goldschmidt reduces it by aluminium; electrolysis of its fused salts is difficult because of their high melting points. If electrolysis of aqueous solutions of chromium salts could be satisfactorily controlled, so as to produce heavy deposits, this might open the door at once to cheap and pure chromium. Electrolysis of molten relatively fixed salts in which chromium oxides are dissolved (similar to the Hall aluminium bath) is not a hopeless proposition. The chromium would be plated solid, however, on chromium cathodes, since the working temperature would be below the melting point of chromium.

The metallurgy of chromium is full of attractive possibilities, and the usefulness of pure chromium in the field of alloys is only beginning to be scratched; the scratching, however, is proving very much "worth while."

Titanium

Our friend Mr. A. J. Rossi and the Titanium Alloys Manufacturing Company of Niagara Falls are the *alpha* and *omega* of the titanium industry. Nearly fifteen years ago my first introduction to Mr. Rossi was in the historic barn at Niagara, the cradle of so many of the Niagara Falls industries. Mr. Rossi was running the electric furnace and Mrs. Rossi was in the little laboratory making the necessary analyses.

Everyone knows of the enormous masses of titanic iron ore in northern New York and Canada, which contains so much iron and so little sulphur and phosphorus, that every blast furnace would be glad to get it if it was not for the titanic oxide, which makes it so unworkable that you could not give it away to them. Mr. Rossi tried first to extract the iron only, throwing away the titanium in the slag, but that was not profitable. He then turned to producing ferro-titanium alloy for use in steel and cast iron, and by indomitable perseverance has made that a success. A finely written booklet of over 100 pages, published by his company and to be had for the asking, tells the whole story, so why take up time to rehearse it here? Get the booklet and read it.

In addition to titanium treatment of steel, to deoxidize and denitrogenize, this company also makes a specialty of titanium-treated aluminium bronze, also of titanium-treated bronzes and brasses of various compositions.

With titanic iron ore carrying 10 to 15 per cent of titanium as cheap as iron ore, and if iron-free material is required, rutile, 60 per cent titanium, at 5 to 7 cents per pound, there is no lack of cheap raw material. If

uses are found for pure titanium, however, some other than the electric furnace must be used to reduce it, because, in absence of iron, titanium carbide would result. The methods for producing pure titanium are, like its prospective uses, still in the future, but they nevertheless are worth study and work. One can buy titanium metal now at about the price of silver, but if the problem were properly faced it could probably be made as cheaply as chromium.

Molybdenum

Molybdenum sulphide, MoS_2 , 60 per cent molybdenum, looks almost exactly like graphite, and is about as widely distributed. Normally, it can be purchased as 90 per cent concentrates at 25 cents per pound. This would make the raw material for 1 lb. of molybdenum cost nearly 50 cents; the selling price of the metal is about \$2. This leaves a large margin to pay for reduction. In fact, \$1 per pound of contained molybdenum ought to return the reduction works a good profit.

However, the principal need of the molybdenum industry is a better utilization of its sources of raw material. The deposits have not been, in general, properly prospected or opened up, and then not properly worked. They are usually low-grade propositions, with 5 to 10 per cent of molybdenite disseminated through hard rock. This calls for careful study of crushing and concentrating methods, so as to minimize waste and loss. In most cases, the actual treatment falls far short of this, and possibly half the molybdenite in the ore is lost. The producers of the concentrates are being paid high prices for their material, but the market is limited and dull. If molybdenite were sold cheaper, there is little doubt that ferro-molybdenum, 50 to 85 per cent molybdenum, could be sold at half its present price, and the uses of molybdenum in steel correspondingly increased. New uses have also been found, such as the molybdenum wire so useful in electric resistance furnaces. This wire is scientifically very useful in that it resists the alloying action of many liquid metals even at very high temperatures. Dr. C. G. Fink of the Edison Lamp Works has studied these notable physical and chemical properties, and has described them in the *Transactions of the American Electrochemical Society* (Vol. XVII, page 229, 1910).

Zirconium

We may mention this element, which, as metal, is rare enough, but whose oxide has recently been found in considerable abundance. The familiar mineral zircon is the silicate, containing nearly 50 per cent of zirconium, but it is found only in limited amount. In the last ten years the oxide, baddeleyite, has been found in large quantities in Minas Geraes, Brazil, running 75 to 95 per cent pure, giving 50 to 75 per cent of the metal. This source is now so common that it sells at 4 to 5 cents per pound, and is being used in large quantities as a refractory material, on account of its high melting point (2000 deg. C.), high resistance to all kinds of slags, low thermal conductivity and low coefficient of expansion.

The metal, however, is almost an unknown quantity. It has been obtained by the action of potassium or sodium on the anhydrous fluorides. Fused, it is white, density 6.4, melting point 1500 deg. C., hard enough to scratch quartz. Ferro-zirconium has been made in the electric furnace and used in small amounts in steel with rather indefinite results. And yet, if some very useful proportions of zirconium were discovered, the metal could undoubtedly be prepared at a reasonable price—only a fraction of the \$5 per ounce now asked for it as a chemical curiosity. How it is to be obtained cheaply

is one more of the interesting questions confronting the metallurgical pioneer.

Cerium

There is a peculiar interest attaching to this metal and its close associates, from the fact that hundreds of tons of fairly rich cerium material is lying on the waste heaps outside of the incandescent mantle factories. The thorium ore used by these factories is monazite—a phosphate of the cerium earths plus thorium silicate. On extracting the thorium, the residue is worthless for mantle fabrication. It is known as "commercial cerium carbonate," and contains cerium, lanthanum, neodymium, praeosodymium, samarium, gadolinium, yttrium, ytterbium, a little thorium, and considerable alkalies, iron, phosphoric acid and silica. By treatment with acids, precipitation of the rare earths, and ignition, a chocolate-brown mixture of oxides of the rare earths is obtained, in which cerium oxide predominates, and which contains nearly 50 per cent of metallic cerium. When this mixture is reduced directly, without further separation, to the metallic state, an alloy of the rare earth metals is obtained which is known as mixed metal (mischmetal) or impure or commercial cerium. The composition of mischmetal naturally varies, but may be taken as approximately 30 to 50 per cent of cerium, 15 to 25 per cent of lanthanum, 10 to 15 per cent of the didymiums, up to 20 per cent of the yttrium metals, and 1 to 5 per cent of thorium.

An immense amount of laboratory and practical work has been expended on the production of mixed metal and of purer cerium. Professor Muthmann and his students in Munich and Alcan Hirsch in the United States deserve particular mention for their articles, in *Liebig's Annalen* (1902 to 1910) and *Transactions American Electrochemical Society* (1911) 20, pp. 1-102, respectively. Dr. Auer von Welsbach was the pioneer in the commercial manufacture and use of mischmetal. Annoyed by the sight of heaps of the cerium residues around his mantle factories, he experimented with their reduction to mischmetal and with the possible uses of the latter. Finding that it gave off sparks when scratched he conceived the idea of using it in automatic lighters, but found that it sparked far too feebly and unreliably to be practical. He then thought that if he purified the cerium it might give sparks more freely, but on making the purest cerium he found it to spark less than the impure metal. Turning in the opposite direction, he took mischmetal and added to it alloying metals not of the rare earth class, and found that they increased the sparking property. Iron, for instance, when increased to 30 per cent gave an alloy with remarkable spark-giving properties, such as make it most efficient and reliable in automatic lighters. This has formed the basis of the 'pyrophoric alloy' industry, since although other metals have similar effects the 30 per cent iron alloy is probably the best sparking alloy, for general use, so far made.

The electrolysis of fused cerium salts, double chlorides or double fluorides, to give the melted mixed metal is carried on on a large scale in Austria at Treibach, in Germany near Berlin, and was commenced in the United States, in 1916, near New York City, by Mr. Hirsch and his associates. The technique is not easy to master, and all the works keep their operations as secret as possible. The principal difficulties are the resolution of deposited metal, metal fog, and scattering of the metal as fine globules or 'metal-mush' through the electrolyte, making it difficult to unite the metal to one melted mass. Since the latter trouble is largely due to surface tension, a study of this property, particularly how it can be diminished, might help in overcoming the difficulty. As an example of the opposite effect, the

cupelling of lead on a bone-ash muffle depends absolutely, for its success, on the surface tension of the molten lead. But, metallic tellurium, in quite small percentage, *decreases* the surface tension of the lead so greatly that the metal *wets* the cupel and cupellation is rendered impossible. Arsenic, on the other hand, *increases*, the surface tension of melted lead, and is therefore purposely added to it, about 0.25 per cent of it, to lead being made into lead shot, in order to make rounder shot.

A physical investigation of such effects on cerium might well assist in overcoming the scattering of the metal in globules in the electrolyte. Another direction in which improvement might be made would be the careful study of the eutectics of mixtures of cerium salts with barium salts, so as to find an electrolyte of lower melting point in which the losses by re-solution of deposited metal would be less than they are at present. Another possible improvement would be the finding of an electrolyte which would dissolve cerium oxide or the mixed oxides directly, and give metal by electrolysis. Such a bath has been discovered for aluminium oxide, and a long experimental search for a similar bath for the cerium oxides would be amply justified.

The possibility of using the 30 per cent iron alloy as a melted cathode, and enriching it in cerium by electrolysis, might be considered. If we had the fusing point curve of cerium-iron alloys we could draw some useful conclusions in this direction. The addition of small amounts of other metals to the bath, so as to produce other useful cerium alloys directly, might facilitate the electrolytic operation. Further experience with the process, particularly by those familiar with the electrolysis of molten baths for sodium, magnesium or aluminium, will very probably lead to considerable improvements and reductions of cost.

The uses of cerium and particularly of its alloys is sure to increase, and may attain considerable proportions. It has been proposed by Borchers as an addition in small quantity to aluminium, to improve its properties. But the large use will always be the pyrophoric alloys, which have so largely replaced matches. Before the European war, over 3000 workers were employed in Austria in this industry of pyrophoric alloys and automatic lighters. Mistakes were made in the early days of the industry, and some alloys put into lighters which crumbled to pieces by the time the apparatus reached Australia, but continual improvement was being made, until a satisfactory substitute for matches was attained. The improvement most needed in the pocket lighting apparatus is to be able to dispense with alcohol or similar liquid; a wick impregnated with a *solid* combustible which can be ignited by a pyrophoric alloy, would give a great impetus to this art.

The author apologizes for making this paper so largely critical and prophetic. If it has sounded too prospective in tone, the excuse must be that it is inherent in the subject. Some of these elements are among the most common in nature, yet they remain so rare in practical life that they are still chemical curiosities. But the chemical curiosities of one age have frequently become the chemical commonplaces of the next age, and even within a generation some of us have seen this happen, under our own eyes. Let us then be foresighted, forehanded, and anticipate possible developments a little by such a general review as has just been given, so that when some wonderful changes and improvements are made in the next few years we may have the satisfaction of knowing that we glimpsed their shadows some time before they arrived, and may even have assisted in hastening their arrival.

Refining Vegetable and Animal Oils*

BY CHARLES BASKERVILLE, PH.D., PHARM.

The terms "fat" and "wax" are commonly applied, more or less indiscriminately, to solid substances which have a greasy feeling to the touch and do not dissolve in water. Physically, waxes are regarded as having generally a harder consistency than fats. Chemically, fats are usually compounds of the trihydric alcohol, glycerol, $C_3H_5(OH)_3$; while the waxes are compounds of monohydric alcohols of large molecular weight; for example, cetyl alcohol, $C_{26}H_{54}OH$; myristic alcohol, $C_{14}H_{29}OH$, and cholesterol, $C_{27}H_{46}OH$. The names applied to some of these substances do not lessen the confusion; for example, "wool fat" and "spermaceti" are compounds of cholesterol and cetyl alcohol, hence are in reality waxes; while "Japan wax," a compound of glycerol, is actually a fat.

A fat, such as is indicated above, has among other physical properties a characteristic melting-point. Those which are liquid at ordinary temperatures are called *oils*. It is of such substances more especially that this communication deals with, although reference will be made to coconut oil, which may or may not be a solid at ordinary temperatures, therefore technically might be regarded as a fat.

It will be understood that the term "oil" as here used, is not to be associated with the natural or petroleum oils, *i.e.*, hydro-carbon oils, or the essential oils, both classes of which in general exhibit in a way the physical but not the chemical properties, necessarily, referred to above.

Fats are widely distributed in the vegetable and animal kingdoms, and, referring to the former only for the time being, we may say they are primarily glycerides of oleic, palmitic and stearic acids. These fats are found *mainly*, but not necessarily, in the reproductive bodies, such as spores and seeds. They are found in spores, sexual and asexual, of many *algæ*. In angiosperms they are widely distributed, replacing, wholly or in part, carbohydrates as reserve food material, and they are often associated with protein reserves; for example, in the seed from which colza oil, palm oil, cotton-seed oil, linseed oil, olive oil and cocoa butter are obtained. It is present, perhaps, as a reserve food material, associated with starch, in some tubers. The starch in the parenchyma of the stem of certain plants may be converted into fat during the winter's cold, and *vice versa*, when there is a rise of temperature in the summer time. Without venturing into the misty etiology involved, we may, for our purposes realize the likelihood of the presence of carbohydrates, proteins and other substances derived therefrom, as gums, etc., in oils obtained from these sources by the various means to be referred to later.

These oil-containing bodies invariably contain some coloring matter. Some of the coloring matters appear to be essential for certain of the changes just referred to. The most prominent pigment appears to be chlorophyll, an ester of tricarboxylic acid, chlorophyllin, $C_{55}H_{72}N_4Mg(COOH)_3$, and is the normal green coloring matter of plants. It may easily be broken down into substances that contain magnesium and substances that do not contain that metal.

Accompanying the chlorophyll are several pigments more or less insoluble in the cell sap; namely, carotin, $(C_{40}H_{56})$, yellow to red in color, and xanthophyll $(C_{40}H_{56}O_2)$, a neutral body, yellow to orange in transmitted light. These substances may be destroyed by the action of such powerful chemical agents as concentrated sulphuric acid, especially if heated in the presence of oxygen.

Closely related to the fats is a group of substances known as phosphatides or lecithins. Occurring in egg-yolk to about 9 per cent, we find them to the extent of from 0.25 to 1.75 per cent in cereals and leguminous seeds, hence they appear in the oils extracted from the seed. They are glycerol esters, two of the acidities being neutralized by fatty acids, the third being saturated by a combination of phosphoric acid and choline, as shown here:

It is easily broken up by lipase, and hydrolized by boiling with alkalis and acids.

We always also find a small quantity of unsaponifiable residue in fats, which is in the main composed of the monohydric alcohols, cholesterol, $\text{C}_{27}\text{H}_{46}\text{OH}$, and phytosterol, the latter now being a generic term for a group of allied substances, with formulas varying from $\text{C}_{28}\text{H}_{48}\text{OH}$, (sitosterol) to $\text{C}_{30}\text{H}_{50}\text{OH}$ (stigmosterol). Cholesterol occurs in the bile, brain and blood of animals, and is the chief alcohol constituent of wool-fat. All vegetable fats contain phytosterol, the amount varying from 0.1 to 0.3 per cent, being even higher in the oil obtained from certain peas and beans, especially Calabar beans.

The oils are extracted by disintegration of the mass involving a disruption of the oil-sacs: (a) with a suitable solvent; (b) rendering by heat, with or without water; (c) or pressure, mechanical, applied when the mass is cold or hot.

If the mass extracted be selected and perfectly clean and fresh, the oil or fat obtained is usually neutral and "sweet." The exigencies of commercial operation do not admit of these conditions, however, so the oil or fat produced is usually acid and more or less contaminated. The contaminations may be quite normal and natural. They may be bacterial in nature and also contain the very interesting substances known as enzymes (lipase, for example) which induce hydrolysis; that is to say, they will cause any water present to disintegrate the fats (and other bodies) into simpler bodies. This may be facilitated by exposure to air and light, so that a freshly expressed oil that is sweet may soon acquire an unpleasant taste and odor. In some cases we say it becomes rancid, but in all cases the oil develops acidity, and the amount of the acidity of a particular oil is a function of time.

Under favorable conditions—and they are usually favorable—these changes take place within the oil-containing bodies, so that freshly produced oil is usually acid, which acidity increases on keeping. The enzymes are "killed," or decomposed, or at least their directive activity ceases when they have been exposed to a temperature of about 200 deg. C. It has not been considered a good procedure by the practitioners of the art of oil extraction and refining, however, to heat the oil to such a temperature immediately after its production; but I venture the opinion that the increased development of acidity in crude oil in storage or in transit to a refinery will be materially affected by such treatment. However, it will be necessary to be assured that substances charred or scorched at that temperature are absent.

As mentioned above, oils and fats are primarily glycerides of the saturated palmitic ($\text{C}_{16}\text{H}_{32}\text{O}_2$) and stearic ($\text{C}_{18}\text{H}_{36}\text{O}_2$) acids, associated with the fatty acids of several unsaturated series. For example:

1. Oleic acid, $\text{C}_{18}\text{H}_{34}\text{O}_2$, type $\text{C}_n\text{H}_{2n-2}\text{O}_2$.
2. Linoleic acid, $\text{C}_{18}\text{H}_{32}\text{O}_2$, type $\text{C}_n\text{H}_{2n-4}\text{O}_2$.

3. Linolenic acid, $\text{C}_{18}\text{H}_{30}\text{O}_2$, type $\text{C}_n\text{H}_{2n-6}\text{O}_2$.
4. Clupanodonic acid, $\text{C}_{18}\text{H}_{28}\text{O}_2$, type $\text{C}_n\text{H}_{2n-8}\text{O}_2$.
5. Ricinoleic acid, $\text{C}_{18}\text{H}_{34}\text{O}_3$, type $\text{C}_n\text{H}_{2n-2}\text{O}_3$.

The last is an hydroxy acid, which undergoes a particular polymerization under suitable conditions.

Most fatty oils, on exposure to the air, tend to thicken, due partly to oxidation and partly to polymerization, or both. Oils are, in fact, classified by many according to their drying qualities and tendency toward resinification. These properties play an important part in their utilization in the arts; and their treatment in refining is materially affected by the time which may have elapsed from actual production to their refining. For example, a freshly produced linseed oil may be profitably refined by a process which is inapplicable if the oil be "aged oil."

Oil, as stated, is normally a liquid, and we usually associate the phenomena of solution with a liquid. To be sure, this is a restricted conception, but will answer for our purposes. In this connection oil acts like water as a fluid. Water in motion carries fine particles suspended through long distances and deposits them in time, when fairly quiet, as we know from the formation of alluvial soils. Water carries certain substances in solution. These latter substances are sometimes colored and are partly fixed on the filter when that water passes through certain filtering media. For instance, we are able to adsorb Congo red from a water solution with filter-paper. Again, water carries certain substances which do not stop on the filter; they are invisible and show themselves only when we apply the ultra-microscope. These finely divided substances, not small enough to be in actual solution, will remain suspended in the water for long periods of time. They are called colloids. By various means, through heat, addition of an acid, an alkali, or a salt, by the influence of an electric current, or by the addition of other colloids, these very finely divided substances may be caused to agglomerate; that is, they may be converted into particles of sufficient size to be separated from the fluid by means of a filter. Exactly the same is true of oils. Organic colloid solutions may be viscous; the liquid particles are suspended in a liquid medium.

Many of the contaminating substances, referred to here in general, may be suspended in the oil, may be in solution in the oil, or may be in a colloidal condition in the oil.

It will, therefore, be quite apparent that crude vegetable and animal oils contain a variety of impurities traceable to a great variety of causes. The character of the crude oil depends not only upon the kind and part of the vegetable (wood, nut, seed, etc.) and animal (fish, whale, etc.) used, but the quality of the raw material at the time of expression or extraction (rusting, rotting, fermentation, sprouting, heating, etc.) the method followed, the care exercised in the process, and the conditions to which the oil is subjected prior to its refining. In many cases, in fact, we find metallic soaps present in the crude oil, which soaps have resulted from an interaction of decomposition products of the oil and the rendering vessels.

No universal method for refining animal and vegetable oils is known. Your forbearance will not be taxed, however, even were it profitable, in discussing all the various proposals for fitting these oils best to the several purposes experience and practice have shown them to be applicable. A number of processes have been proposed, patented, or kept secret during the last 125 years. Around the knowledge and power of the practical oil refiner not a little mystery still obtains. Each individual oil presents its own problem, and even the same oil by name, obtained under different conditions, involves judg-

ment based on the knowledge of the chemistry involved, to secure the best and most economical results. Furthermore, the use to which the oil is to be put must be considered; for example, one wants acid oil for some paints and neutral oils for foods.

Some four general methods for refining oils have been and are being worked in practice. They are:

1. Treatment with steam (plain or superheated) whereby some coagulation results and many odoriferous substances are driven off. This does not diminish the free fatty acid content of the oil so treated.

2. Treatment with variable amounts of concentrated sulphuric acid (Gower, 1792) under determined conditions of heat and agitation with or without air. The oil contains certain substances which, when flocculated by the acid and temperature, fall down and mechanically (term used in several recognized authoritative books) carry down other impurities. This process does not diminish the acid content of the oil so treated.

3. Heating up under carefully regulated temperature conditions with fullers' earth, bone-black, etc., and filtering. This process also yields an acid oil.

4. Adding caustic alkalies, or alkaline earths, of an amount and strength determined by laboratory experience (Barreswil, beginning nineteenth century), heating to the "break," settling and drawing off the oil which floats upon the soap stock or "foots." This was supposed to give a neutral oil, but not until it had been washed several times with water.

Yet as late as last year a distinguished oil chemist, in a very interesting summary of the "Contributions of the Chemist to the Cotton-seed Oil Industry," said: "The chemist . . . found that the quality of the oil followed the free fatty acid present." An empirical formula has been worked out to show this relationship to the free fatty acid. The rule is: Multiply the f. f. a. by 2 and add 4; that is, an oil showing 2 per cent f. f. a. should give a shrinkage of 8 per cent. This is true only in a general way. I recently had a cotton-seed oil with 1.7 per cent f. f. a., which showed a shrinkage of 21 per cent by the official method of the Cotton-seed Crushers' Association.

The writer quoted above further said: "The chemist's greatest service to the industry has been in the refining of the oil . . ."

Wesson was here referring more especially to edible cotton-seed oil. In that connection Lewkowitsch, the lamented Anglo-German specialist in oil chemistry and technology, has said: "No chemically treated oil or fat can be looked upon as a product fit for human consumption." I confess inability to comprehend this sharp distinction as to what is meant by a "chemical." Oxygen from a chromate is a chemical; oxygen of the air is not. Sulphuric acid is a chemical; caustic soda is not. It may be interjected here that certain statements transmitted by texts and sanctioned by law call for clarification and revision. No treatment of an oil or fat, which involves purification, rendering it palatable, agreeable to the sight and avoids the introduction of constituents which may interfere with normal digestion should be forbidden. For fear of misunderstanding it may be stated here that the method described below complies with all the most rigid laws of all nations and even the above-mentioned uneven discriminations.

An oil that is acid is unsatisfactory as a food. Acid oils corrode the vessels and generate objectionable gaseous products when used as burning fluids. Acid oils corrode the bearings when used as lubricants, so it is desirable to have neutral oils for many purposes. Yet a neutral oil does not "cut" into white lead, for example, so an acid oil is preferred as a paint vehicle; but Gardner has pointed out that the oil should not be too acid.

I have been more concerned with neutral oils and their production, so shall confine my remarks to preparation of that class of substances.

The present customary practice for refining vegetable oils referred to (the fourth mentioned above) depends upon neutralizing the free fatty acids in the crude oil usually by agitating the oil with an aqueous solution of an alkali, the strength and the amount having been previously determined by laboratory tests, agreed upon as a standard, and then heating the mixture during agitation to a suitable temperature until the oil "breaks." The mass is then allowed to stand until the "foots" settle to the bottom of the kettle, when the supernatant oil is drawn off by means of a swivel siphon. According to the process of Chisholm, sodium silicate is added to facilitate the settling. Invariably some "dreg" floats on top of the oil. If this be very great its settling is sometimes facilitated by throwing salt on top of the oil in the kettle. The salt drags down some of the floating "dreg." In any event the oil drawn off is clouded, perhaps on account of the presence of some dissolved soap or globulated moisture or suspended matter—all doubtless colloidal in nature. This oil is then "brightened" after drawing off by throwing in small amounts of fullers' earth, heating again, and passing through a filter press. Sometimes, previous to this treatment with fullers' earth, the decanted oil is heated to 160 to 180 deg. Fahr. in a settling tank to cause the "foots" remaining in the oil to rise to the top, when it is skimmed off.

The time factor in settling (six to twelve hours) of the "foots" materially affects the completeness of the separation referred to above. Coconut oil sometimes requires forty-eight hours to settle. In any event the "foots" is wet with oil. The "foots" also entrains oil. Consequently during the rush season the efficiency of yield of refined oil must be sacrificed for speed and quantity refined. In other words, the more speed in refining, the more loss of refined oil, whatever the analysis, upon which purchase and sale are based, may indicate.

A process which would reduce the amount of oil entrained in the "foots" to a minimum, thus increasing the yield of refined oil, and one which would not be dependent upon the slow subsidence of the "foots" (that is, admit of rapid separation with consequent increase in capacity of a refinery), therefore, seemed to me not only to be desirable, but, if secured, would approximate the highest efficiency one might hope for in such an industrial operation.

I have succeeded in working out such a process, and shall now proceed to describe the principles involved and at the same time demonstrate it to you as an analytical method. I have pleasure in exhibiting to you samples of the crude and refined (by my method) oils from a variety of sources.

The technical laboratory tests with batches of twelve to twenty pounds have been verified in the factory on a commercial scale. Some of the samples exhibited are from factory runs.

The aims to be accomplished are:

1. To reduce the amount of oil entrained in the "foots," thus increasing the yield of "whole oil."
2. To reduce the time of contact of the excess alkali (necessary for the "break" and to secure the best "color") to the minimum.

3. A technological corollary calls for the utilization of any by-products.

It is to be assumed that all oils, good, bad and indifferent, are to be treated. However, this may not be necessary, as in some cases only the good, and perhaps the indifferent, oils are refined under the old practice at some places. Certain foreign markets call for a highly

colored oil, so they do not present the problem of bleaching.

In my investigations, lasting through several years, I have taken various kinds of crude vegetable oils from various kinds of sources with various (extreme) conditions and refined them. In many cases I have been told that no attempt would ordinarily be made to refine a particular oil, as it should be sent to the soap kettle, the corresponding price only being expected. Such oils would have represented much better values if they could have been refined by the usual practice. These oils in every case have yielded to my process, have been refined, and with a saving over the old processes. I may say, however, that China wood (tung) oil, castor oil and aged linseed oil cannot be economically refined by the process. I wish also to repeat that I am referring to the production of neutral refined oils only.

FIG. 1—COMPARATIVE LOSSES FOR COTTON-SEED OILS

If we can get the "foots" into such a condition that it may be filtered and then squeezed, we may reduce the amount of "whole oil" entrained.

If we can do this immediately after the "break" and while the oil is still hot, we shall be able to reduce the time the "whole oil" is exposed to the saponifying action of the excess alkali necessary to secure proper color, avoid the present practice of necessary "cleaning," and the second heating.

I have called your attention to the presence of bodies, which in general terms are called colloids, in oils. These colloids may or may not be colored; may or may not make the oil turbid. I have also shown that some colloids may be and are coagulated by heat, some by acids, some by alkalies, some by salts or electrolytes, and in time will settle out. Colloids that have been coagulated or lumped may be filtered out. Some coagulated colloids in their formation adsorb coloring matter. The problem

of economical filtration on the large scale necessary was one of great difficulty; in fact, so far as I am aware, it was unsolved previous to my investigation. Suitably prepared cellulose fiber will adsorb some coloring matter. It will bring about an agglomeration of the material precipitated from oils by treating the oil with alkalies and heating, and it will bind the particles together so that they may lose their somewhat slimy character and then may be easily filtered away from the oil in which they are produced. Short-fibered "inters" or "delint" is a suitable form of cellulose for some oils.

Therefore I add cellulose, suitably prepared, along with the caustic to the oil to be refined. The "break" takes place normally on heating as in the ordinary process, but the precipitated mass is in such a physical condition that it may be separated from the oil immediately by filtration.

As mentioned above, some colloids, perhaps colored, are thrown down by salts, so in certain cases some salt (1 per cent of sodium chloride) may be added. If there be a slight excess of water present, the sodium chloride serves also to "salt out" and soap in that water. The addition of salt, however, is not necessary in all cases.

I have also discovered that the tendency of the soaps formed by the caustic-alkali treatment to emulsify with the oil, or so to distribute themselves through the oil as to render their separation difficult, may be overcome by subjecting the oil, at a suitable stage of the treatment, to the action of an anhydrous salt which is capable of taking up water of crystallization, the preferred salt being dry sodium carbonate (soda ash), which, as is well known, is capable of taking up one, seven, or ten molecules of water of crystallization, according to temperature conditions. By such treatment the soaps which have already been formed by the treatment with caustic alkali, and which have become so incorporated with the oil as to be incapable of complete separation by ordinary filtration, are hardened or pectised, presumably by dehydration, and are so modified that they are readily separated by simple filtration. Sodium sulphate, which acts in the same way, may be used instead of soda ash.

The process is carried out by adding ordinarily 2 per cent of prepared cellulose (less than 1 per cent real cellulose) and a suitable amount of caustic soda (usually much stronger but actually less in amount than is commonly used). The whole is thoroughly basted by mechanical means and then heated to 45 to 65 deg. C. to produce the "break"; a determined amount of soda ash is added, after which it is filtered. At first some soap may pass through the filter-cloths. In that event, the first filtered oil may be run directly back into the refining kettle and pumped through the press until the oil is "bright." This usually occurs within a few minutes; in fact, the speed of filtration is directly dependent upon the speed of the pumps. This re-filtration also improves the color. This oil is neutral and can be deodorized and bleached, or both at once, or may be

FIG. 2—COMPARATIVE LOSSES FOR SEVERAL OTHER OILS

stored safely. If linters is used, $\frac{1}{4}$ to $\frac{1}{2}$ per cent of the dry cellulose is added.

These ideas are covered by four United States patents granted, Nos. 1,105,743, 1,105,744, 1,114,095, 1,130,698, and others applied for.

The danger of making a whole kettle into soap stock through failure of the refiner to be "on the job" is reduced to a minimum, as in several thousand trials this has not occurred, the trials being made by different people with various grades of oils of different character. In other words, the process is near "fool-proof." Any man of fair intelligence can operate the process, and the air of mystery surrounding the professional refiner is dissipated. The superintendent has a double check on the refinery by weighing the finished oil and cake. The daily reports when summed up should coincide with the annual inventory. I have known of cases where as much as 100,000 pounds of oil have failed to appear in the annual inventory, but were reported daily and had to be charged up to profit and loss at the end of the fiscal year when the operation was under the usual process.

The curves of Fig. 1 have been prepared from a series of cotton-seed oils very variable in character. Fig. 2 shows the comparative losses with several other oils. They show the comparative losses by the normal present practice and my process.

I have also been able to secure a further 1 to 3 per cent saving by subjecting the "cake" to hydraulic pressure. This extra saving is not shown in the charts.

The process is very rapid, the controlling factor being filter-press capacity. A study of plate filter-presses has indicated a preference for a center-feed press making $1\frac{1}{2}$ - to 2-in. cakes. The filter-press problem in connection with the process is not one of filtering area, but cake capacity. Presses, as the Kelly or Sweetland, which are dumped mechanically, meet the conditions better than plate presses. A new Sweetland press recently devised for this process promises the best results. It is provided with bottom exits for the refined oil, and the under bivalve swings through an arc of 165 deg. Monel metal filter-cloth makes the machine practically permanent. By a slight increase in filter-press capacity the output of a refinery may be doubled or even tripled.

UTILIZATION OF BY-PRODUCT

The cake may be converted directly into soap, the cellulose becoming very finely comminuted. It is partially mercerized, partly converted into a colloid, and some of it forms an unobjectionable filler for some grades of soap, especially soap powders.

The cake may be "cut" with acid directly. The cellulose settles quickly in the aqueous layer from the black grease, which latter may be drawn off ready for market or use. When the cake is to be "cut," in order to reduce the amount of acid necessary, I prefer to use salt cake in place of soda ash as the "agglomerator."

A solution of niter cake, the process of Dr. Jeffrey Stewart of Philadelphia, patent assigned to the du Pont de Nemours Company, for the recovery of oil from soap stock, can also be used in cutting the cake. In view of the high price of acid at present, this may serve as an economical method for making "black grease."

Printed instructions for the use of the method in practice or as analytical procedure will be supplied to any who will write for them.

SUMMARY

A process has been worked out, based on scientific principles, for preparing neutral oils, which possesses the following advantages:

1. The actual refined oil obtained is from 1 to 10 per cent more than now secured. Placed at a low average of 3 per cent, the process will save the cotton-seed oil

industry in this country over \$2,000,000 a year when prices are normal. The soja-bean oil industry, just developing in this country, can save 5 per cent. The peanut oil industry can save 6 per cent. The coconut oil industry can save from 3 to 5 per cent.

2. The process takes from one-tenth to one-third the time now necessary. Hence the capacity of the refinery is increased. This is of great importance during the rush season; in fact, its introduction will in economic efficiency perform the same rôle the tungsten filament lamp has played in the electric lighting industry, whereby the light production of a power station has been tripled.

3. The process gives a daily double check on the efficiency of the refinery.

4. The process is applicable to all grades of edible oils, which is not true with the common procedure.

5. Little new machinery is needed. The extra filter-press capacity called for will be more than paid for in the first year's profit.

6. The cost of chemicals is the same or less.

7. The by-product cake may be converted directly into a useful and commercial material.

Roentgen Rays and Crystal Structure*

(From *Lancet Engineering*, June 2)

To the general public the Roentgen rays remain the X-rays—the name chosen by their discoverer—a scientific mystery, more fascinating than radium, which, after all, does not do much more than shine and decay, a thing a conservative mind does not approve of. That in decaying radium generates helium, and that the disintegration proceeds through an extraordinary series of stages, ranging in time-period from minutes to thousands of years, is hardly understood by people who are quite able to appreciate the wonderful things that medical men have achieved with the aid of Roentgen tubes.

But the rays have done much more. They have helped to establish the actual existence of the atom and to reveal that the atom itself has a structure, and they promise to disclose the structure of the atoms in crystals—i.e., the way in which the atoms are grouped and arranged in solids. The student of elementary science soon grasps that solids are dreadfully complex by comparison with gases. The chemist can analyze solids as well as fluids. He splits a compound into its constituent elements, finds out the relative numbers of atoms of each constituent, counts, in conjunction with the physicist—for it is mainly physical chemistry, of course—the actual number of molecules or atoms, and assigns definite structures to the constitutions of certain substances. Those constitutions are not mere speculations; for compounds have synthetically been built up from their elements on the basis of these researches.

But there science seemed to find its limit. Calcite, it has long been known, is CaCO_3 , like limestone; in the kiln the carbonate behaves as if it were made up of CaO and CO_2 ; in solutions it seems to split into the ions Ca and CO_2 . How are the atoms of Ca , C , O actually grouped in the crystal? If they were differently grouped, their properties would probably be different. What are the forces and the laws? The X-rays promise to answer these questions.

The X-rays first puzzled scientists by penetrating through opaque substances and by refusing to be reflected, refracted, or polarized. But there was a strong suspicion almost from the first that they were, after all,

*An account of the work of the late W. H. Bragg, F.R.S., on the structure of crystals, published in our issue of June 15, 1916, under the title "The Structure of Crystals."

only rays of light, though of a light of extremely small wave-length, too delicate to be examined by ordinary apparatus. That assumption has been fully confirmed. The wave-length of sodium light is 5895×10^{-10} Angström units (A.U.), or 5895×10^{-4} cm., and X-rays have wave-lengths of the order of 10^{-8} cm., about one ten-thousandth of the length of ordinary light waves. In a diffraction grating the spacings between the lines should be of the order of the wave-length of the incident light; that condition is fulfilled by ordinary gratings with about 20,000 lines to the inch. To rule a grating with 10,000 times as many lines would be out of the question; the distances between the lines should be of the order of inter-atomic distances.

The ingenious idea occurred to Prof. M. von Laue then (in 1912) at Munich (he accepted a call to Zürich soon afterwards) to make use of the ordered array of the atoms in a crystal as an X-ray grating. The experiments made by Laue in conjunction with W. Friedrich, P. Knipping, J. Herweg, E. Hupka and others, were surprisingly successful; crystals of zinc-blende, copper sulphide, rock salt, diamond, zinc, sulphur, etc., behaved like three-dimensional gratings. That was the origin of the new line of research. The experiments were made by letting a beam of Roentgen rays pass through a crystal on to a photographic plate; the black central spot produced on the plate was found surrounded by small dark spots of greater or smaller intensity, arranged symmetrically to the center and lying on circles or ellipses passing through the center, each spot representing a reinforcement of the waves in that direction. Crystals of copper sulphate gave such a radiograph, the powdered crystals did not. But long exposures (of many hours often) were required, and the interpretation of the radiographs in all their striking regularity, as given by Laue, was very complex; he published a memoir on the "Diffraction of Short Electromagnetic Waves by a Crystal" in the *Berichte of the Bavarian Academy*, Munich, June, 1912.

In a mathematical discussion of this memoir (Proceedings of the Cambridge Philosophical Society, February, 1913), Mr. W. Lawrence Bragg, of Cambridge, proposed a simpler interpretation of the phenomena, which he illustrated by the diagram, Fig. 1. Let a beam

FIG. 1—REFLECTION DIAGRAM

of homogeneous light A, A_1, A_2, A_3 of wave-length λ fall on a series of plane parallel surfaces p (all at the same distance apart d), each of which reflects a small proportion of the incident light and transmits the remainder; then reflection and interference will result as with thin films, except that there are a great many reflecting surfaces instead of the two of the soap film. The wave AB will partly be reflected, at its angle of incidence θ , in the direction BC , and will partly travel on into the crystal; this latter portion is not indicated in the diagram. The waves reflected at B', B'', B''' , etc., will, under certain conditions, pass out in the same direction BC , and in the same phase. To find the conditions, draw BN at right angles to A', B' and produce A', B' until it cuts the plane B'' in D , which will be the mirror image of the point B in plane B'' ; since then $B'B$

$= B'D$, $AB = A'D$, and $ND = B'D$ (the distance by which the rays AB and $A'B'$, and hence also the broken rays ABC and $A'B'C$, will differ) will be $2d \sin \theta$. If DN be equal to the wave-length λ or to a multiple of it, the waves reflected at B and B' and similarly at B'' , etc., will all be in the same phase and reinforce one another. If DN differ only slightly from λ , the difference in phase will become greater and greater as the number of planes increases, and the resultant amplitude at C will practically be zero. Thus reflection (as different from ordinary reflection) will only take place when $\lambda = 2d \sin \theta$. This will be a reflection of the first order, and to mark this we write $\lambda = 2d \sin \theta_1$. If θ_1 be changed to θ_2 , there will be again reflection of the second order for $2\lambda = 2d \sin \theta_2$, and reflection of the third order for $2\lambda = 2d \sin \theta_3$, etc. At angles not satisfying this condition there will be no reflection.

Now in a regular crystal the atoms are probably arranged in parallel planes p , thousands of planes, all at spacings d ; the d may or may not be equal to the distance between two atoms next to one another in the same plane. The planes will not form continuous walls; that is not necessary for reflection, since a cluster of trees or a cloud can reflect sound waves as well nearly as a wall of rock. The atom-bearing planes are set in crystals at intervals of one or two Angström units. The characteristic X-rays used for this study are of the order of about half an Angström unit. This is a pregnant fact, to use the words of Prof. W. H. Bragg; the wave-lengths might easily have been ten or a hundred times the atom spacings, and then the investigation of crystal structure by means of X-rays would have been impossible. The method suggested by Mr. Bragg has been applied with brilliant success by Mr. Bragg himself and by his father, Prof. W. Henry Bragg, up till recently at Leeds, now at University College, London, and in this review we follow mainly the communications made by Professor Bragg, who quite recently lectured upon the subject again before the Institute of Metals and at the Royal Institution. The Bragg method, it may broadly be said, works with reflected rays, while the Laue experiments were with transmitted rays. In their main conclusions the two methods are in entire agreement.

The Bragg relation, $\lambda = 2d \sin \theta$, may be utilized in two ways. When the λ is known, the θ are observed and the d determined; once the d values are determined, the λ can be checked. As the wave lengths λ of X-rays have been measured by independent methods, and the θ can be measured within one minute of arc, the new research admits of considerable reliability. The apparatus used by Professor Bragg is a kind of spectrometer without lenses. A pencil of homogeneous X-rays from an anticathode of rhodium (or some other platinum metal) falls through two narrow slits on a crystal which is mounted on a platform; the reflected ray enters the slit of an ionization chamber (about 5 cm. in diameter, 15 cm. long) charged with a heavy vapor (methyl bromide is now preferred, sulphur dioxide was first used); the resulting ionization is measured by means of an electro-scope and microscope. The crystal or the ionization chamber, or both together, may be turned on the platform to determine the angles at which decided reflection and ionization occur. There is always a slight diffuse reflection from the crystal surface; but the ionization maxima are easily distinguished. As natural crystal faces are often rough or distorted, the crystals are sand-papered or etched with acid, or cleavage faces are taken; elaborate preparation is not required.

The rays used are the characteristic rays of the anticathode; rhodium emits four such rays, or two pairs, the principal ray having a λ of 0.614 Angström unit; the principal ray of palladium has a $\lambda = 0.583$, of silver

0.557 A.U., the wave length decreasing by about 5 per cent as we pass from one atomic number to a higher number (Moseley). The ionization curve found is really the spectrum curve of these characteristic rays; with a rhodium target, therefore, the rhodium rays are repeated in the spectra of higher orders at decreasing intensity; the amplitude of the curve marks the intensity. The method thus does not give any lasting records; the reflected beam might be received on photographic paper—M. de Broglie places a cylinder of sensitized paper round the crystal—but Bragg rarely resorts to photography.

In order to elucidate the relation of the spacings to the crystal form, Professor Bragg calls attention to wall-paper patterns. The position of any point in a pattern may be fixed with regard to two arbitrary systems of parallel lines crossing one another and cutting the pattern up into a number of rectangles or parallelograms. But unless the chosen points of intersection are the same corresponding, representative points, repeating at regular intervals, the parallelogram will not be a "unit" comprising the *ensemble* of the pattern.

Similarly the atoms of crystals are referred to "space-lattices," a kind of scaffolding of three-dimensional axes which, in the cubic system, cross all at right angles and at equal distances apart; in the other crystallographic systems the distances and angles are not all equal. When planes are passed through all the *X*, all the *Y*, and all the *Z* axes, the structure is cut up into cells, cubes, or parallelepipeds. Even the most complicated crystal can be referred to such a fundamental space-lattice, as indicated in Fig. 2. But a cell will not necessarily be a fundamental unit, unless it comprises at least the full number of atoms making up the characteristic molecule (possibly group of molecules) of the substance. Each unit can be considered separately, but to understand the growth of crystals, and the special relations it is better to consider the space-lattice as unlimited in all directions.

FIG. 2—SPACE LATTICE

In the crystal models the axes are represented by wires, and the atoms by beads strung on them. Supposing the atoms to be spaced quite regularly, as in Fig. 3, each little dotted square (in the wallpaper), or each cube on that base (in the crystal), would represent a unit. In the alternating grouping of Fig. 4 each dotted square would again give a cube (1 or 2), but only one of the two (2) would represent a unit (the *c* in Fig. 4 will be explained presently), and in Fig. 5 four of the

ATOM ARRANGEMENTS

little squares would be required to make up a unit. The relations become clearer when small balls (atoms) are piled upon one another, which can be done in various ways; but the wire models are the most instructive, and when they are so held in the lantern beam (as Professor Bragg does) that corresponding axes and atoms coincide, the arrangement of the atoms in the various planes can clearly be recognized.

When the pencil of X-rays falls on the plane *ABCD* (Fig. 2), the formula $\lambda = 2d \sin \theta$ gives the *d* as distance between that plane and the next parallel to it, *EFGH*. When the pencil falls on the plane *A E H D*, the distance of this plane from *B F G C* is determined. But planes may also be passed, *e.g.*, through *E B C H* and corresponding points, cutting off the level of the edge *A D*; again, the nose of the crystal may be cut off, as Professor Bragg calls it, by a plane through *D* and *E B*; and so on. The values of *d* determined in this way may or may not be equal, but they will always be in definite geometrical relations. The larger the angles of reflection observed the closer will be the spacing.

Yet the deduction of the crystal structure from the *d* is not simple. In the case of a cubical lattice, for instance, the atoms may be arranged to cubes in three ways. When experimenting with rock salt (NaCl) and sylvine (KCl)—cubic crystals, very much alike in all properties—Mr. Bragg found that the *d* were not always in correspondence in the two crystals. There was parallelism when the atoms were referred: (a) to a simple cube (one atom at each corner), or (b) to a center cube (one atom at each corner, one in the center of the cube), but when the atoms were referred (c) to a face-centered cube (one atom at alternating cubic corners, one in the center of a face), as in Fig. 4 (c), the analogy between rock salt and sylvine failed. This was found by considering cubic planes, planes beveling off the edges, and planes cutting off the noses, as mentioned, and in this way it was established that KCl gives a simple cube of type (a), and NaCl a face-centered cube of type (c), while ammonium chloride is one of the rare examples of type (b). The face-centered cube (c) is very common, and the crystals of copper, silver, gold, etc., belong to this class.

So far all these measurements were merely relative, however. Absolute determinations of the *d* can be made when the atomic weight and the density of the material are known, and in the case of rock salt the distance between two planes (cubic faces) was found to be 2.81 A.U. The consideration of the relative intensities of the spectrum lines of the various orders constitutes another very important step. The intensity of a spectrum line depends upon the atomic weight of the atoms in the plane. When all the atoms in all the planes are the same, the intensities should diminish, according to a simple law, with the higher orders, just as in the case of a regular grating. That was found to hold for crystals of elements, and nearly to hold for KCl, because the atomic weights of K (39) and of Cl (35.5) do not differ much. But it did not hold for NaCl (Na = 23, Cl = 35.5). If the atoms of Na and of Cl were arranged in alternating parallel layers, the intensities should indeed alternate, just as in the case of a grating ruled with alternating strong and weak lines. Mr. Bragg correctly interpreted these features, and it follows that his value for the *d* of NaCl (above given), *i.e.*, 2.81 A.U., marks the distance between a sodium atom and the chloride atom next to it.

When the spacings between the parallel planes are not all the same, similar intensity variations should be observed. In the case of the diamond there is reason to assume that each carbon atom forms the center of a small, regular tetrahedron, with carbon atoms at the four corners, from which it is equally distant; the lattice is a face-centered cube all the same. When the model is built up, it is seen that the first layer of atoms lies in the base, the second layer at the distance 1 above the first, the third layer at the distance 3 above the second, the fourth at distance 1 above the third, and so on. It is as if a grating were ruled with lines spaced 1 and 3 divisions apart alternately. Such a grating would not

give any second-order spectrum, and the second-order spectrum of the diamond was indeed found absent. The structure of zinc blende (ZnS) is exactly like that of the diamond; but there layers of Zn and S alternate at the distances 1 and 3, and as the atomic weight of sulphur (32.07) is only about half that of zinc (65.37), the second-order spectrum is weak, but not quite suppressed. The structure also would explain why zinc-blende has a polarity, while the diamond has not, for, with the atoms arranged in alternating planes of Zn and S, it would make a difference whether the light rays struck a zinc layer (coming from the left) or a sulphur layer (coming from the right). Professor Ogg of the Cape, at present working at University College, has quite recently found that antimony and bismuth can be referred to tetrahedra, like the diamond, but the central atom is not equally distant from the others in their cases.

We will briefly notice some more complicated cases. Calcite crystallizes in regular rhombohedra, which ought to be perfectly symmetrical about a certain plane. The X-ray examination shows that layers of Ca and of CO_3 alternate in certain parallel planes; in other directions layers of Ca, CO_3 , O, O succeed one another; the symmetry does not appear to be quite perfect, however; that is to say, the left and right half of a section only coincide when the one side has been slightly shifted (gliding symmetry). Dolomite, which is a double carbonate of calcium and magnesium, is found to be built up of layers of Ca, CO_3 , Mg, CO_3 , Ca, etc., and there is no plane of symmetry—which is in accordance with the views of crystallographers. The complicated structure of magnetite ($\text{Fe}_3\text{O}_4 = \text{FeO}, \text{Fe}_2\text{O}_3$) can be imitated by piling up layers of oxygen atoms and fitting iron atoms into the interstices; some of the iron atoms appear as centers of oxygen tetrahedrons (4 O atoms), in which the iron is bivalent, some as centers of octahedrons (6 atoms of O), in which the iron is trivalent; the two sets have some atoms in common and differ by 60 deg. in orientation.

Professor Bragg's wire models, which can be taken to pieces, also help us to understand a puzzling point. The X-ray examination seems to concern itself merely about atoms, and not to recognize molecules. The one Na molecule in rock salt might equally well belong to any one of the six Cl atoms near it. But it is difficult to say in what condition the molecule really exists in the solid, and the X-ray examination does not entirely lose sight of the molecule. The whole crystal behaves like a big multiple molecule. If, in taking the model to pieces, a definite order is observed, the complex crystals of magnetite, as well as the simple rock-salt cubes, break up into their molecules. That shows that there are various methods of breaking up a crystal, and that the surface of a crystal is more or less like an unsatisfied set of atoms, to which set arrangements of fresh atoms will easily attach themselves—an exceedingly fruitful conception, which would account for the growth of crystals as well as for surface adsorption.

When crystals are heated the spacings between the atoms should widen, and the X-ray lines should be shifted and decrease in intensity; rock-salt crystals show this when heated in an electric furnace while being examined. Similarly, the expansion of crystals in different directions could be determined with very small specimens; the method does not require large specimens. The new method may also disclose why soft metals form hard alloys; further, in which way the hard and soft state of metals of Beilby, the surface films and cement films between the crystals, differ from one another. E. A. Owen and G. G. Blake have studied hard and annealed copper by X-rays. The examination, of course, presupposes a regular arrangement such as crystals offer.

Experiments with glass, which is not crystalline, have failed, we believe, as they were expected to do. On the other hand, O. Lehmann has applied Laue's method to the study of liquid crystals; F. Terada has examined rock salt in the plastic state; P. Knipping has discovered a structure in liquid and in solid paraffin and in wax, and S. Nishikawa and S. Ono (likewise experimenting after Laue) discern crystals in fibrous asbestos, arranged along the fillers, but not in glass threads.

In their main conclusions, the two methods, of Laue and of Bragg, are in essential accord with one another, as we have already stated, and that should be so according to L. Ornstein and others. The objections to the former method are the long exposure, the unavoidable (though, in a sense, useful) presence of X-rays of different frequency under these conditions, the difficulty or impossibility of making quantitative measurements, and the difficulty of interpreting the results; according to G. Friedel, moreover, Laue's method does not bring out the full hemihedral symmetry. The quantitative ionization measurements (though not so accurate as the angle measurements) and the rapid working with homogeneous rays are the advantages of Bragg's method; the constancy of the radiation frequency can be checked by the comparison of the intensities of the different order spectra. Absorption, studied by C. G. Darwin, plays a part in both methods. It is satisfactory that Glocker agrees with W. L. Bragg and his co-workers as to NaCl and KCl, with A. Johnsen as to calcite, with E. Keller as to the diamond, and with P. P. Ewald and Friedrich as to zinc-blende, though not as to pyrites. On the other hand, F. M. Jaeger maintains that the theory is so far inadequate, on either lines, to deal with biaxial crystals; there is still one factor missing in the deductions.

X-ray investigation of crystals is young, of course. But there is a dearth of workers, and the war has cruelly put an end to the life of some investigators and has interrupted the work of others.

By-Products from Coke Manufacturers

In a paper presented at the recent meeting of the American Iron and Steel Institute in New York, Mr. William H. Childs, president of The Barrett Company, New York, gave an interesting account of the present status of the recovery and use of the by-products from coking. He pointed out that the development has not been uniform here and abroad. Practically all of the pitch made in Germany, or in Europe, is used for fuel purposes, whereas in the United States the use of the softer grades of pitch has been carefully developed. In the United States coke-oven gas has been used for general city purposes since 1899 with success and increasing favor. Germany did not do this until 1910, but laid great emphasis on the use of oven gas in gas engines for electric power development. In this direction the United States has remained behind. At the present writing new ovens to the number of 2600 are under contract and will probably be completed by the end of 1917.

Many attempts have been made, mostly in gas retort practice, to increase the yield of ammonia from coal, in view of the large amount of nitrogen retained in the coke. The most promising of them seems to be the mixing of a little less than 2 per cent of caustic lime with the coal to be carbonized. Results for a year at an English gas works showed a gain of 1.68 lb. of sulphate of ammonia per net ton of coal, the operations being benefited rather than otherwise.

The latest coke-oven plants have adopted what is known as the semi-direct or direct methods of am-

monia recovery, in which the gas from the ovens, freed from tar, is led directly into the dilute sulphuric acid, the production of sulphate thus being accomplished without the intervention of washing water or redistillation. In the semi-direct system, which is much used in this country, the preliminary removal of tar involves the production of a certain amount of ammonia liquor, which can be treated in a still and returned to the oven gas before it enters the saturator, or can be made into crude, strong liquor. This process is called semi-direct, as all the ammonia is not made directly into sulphate. A direct system, in which no liquor is made, has also been developed and placed in operation in this country.

Some of the German plants put out a dried and ground sulphate, which, being entirely deprived of moisture by kiln drying, tests over 25.25 per cent NH_3 and brings a slightly higher price. A corresponding grade is made in this country.

Several methods have been proposed for making use of the sulphur in the gas to make sulphate of ammonia, rather than to resort to acid purchased from outside. Among these are the processes of Burkheiser and of Feld. The latter seems to offer a prospect of success, though the alterations in the usual methods of gas treatment are quite radical. It has not been tried in coke-oven work in this country as yet, although a modified form is in operation at the Central Union Gas Works in New York City and a plant is being installed at Chester, Pa.

The German cyanamid capacity is now said to be 500,000 tons per annum, and that of the Haber plant, at Ludwigshafen-on-Rhine, 300,000 tons of sulphate of ammonia, this being equivalent to 800,000 tons of sulphate of ammonia, and an increase of at least 500,000 tons over previous capacity. In order to induce private capital to build these plants, the Government has established a nitrogen monopoly, to continue in force after the cessation of hostilities. While the terms of this arrangement are not known, it is highly probable that any relief that they can get by shipping their surplus product into this country will be taken advantage of.

The prospects are that with the full operation of the existing plants, and those that will come into operation before the year is out, the production in this country for 1916 will exceed that for 1915 by 30,000 or 40,000 tons. With upwards of 2600 new ovens under construction, it is highly probable that the years 1917 and 1918 will register successive large additions. It is not out of the way to estimate the sulphate of ammonia capacity of the country at the end of 1917 as 375,000 tons.

Coke-oven gas is, in a way, the joker among the cards in the by-product coke man's hand. It may be worth a great deal for illuminating purposes, or it may be worth only its fuel value as against coal under steam boilers. In the first instance it brings from the consumer, let us say, about 60c. per thousand cubic feet, or, allowing for purification and distribution, about 30c. net. For fuel under boilers the usual price is about 4c. per thousand, depending on the price of the coal it displaces. Modern coking practice easily recovers 6000 cu. ft. of surplus gas per ton of coal carbonized. At 30c. this would be \$1.80 per ton of coal, as against a credit of 24c. which would be the other extreme.

Where a new plant is under consideration there is an ample reward here for wise planning and successful negotiation. Unfortunately, success in finding such a market for the gas is in many cases a difficult matter. For example, a modern plant of, say, 40

ovens, which is about the minimum and corresponds to a 400-ton furnace, would produce about $3\frac{1}{4}$ million feet of gas per day. This, under ordinary circumstances, would supply a city of at least 150,000 inhabitants.

Authentic reports are at hand which show a yield from a recent coke-oven plant of over 12,000 cu. ft. of gas per net ton of coal, containing less than 5½ per cent of carbonic acid and nitrogen. Of this gas less than 40 per cent of the heat value was used in coking, so that the surplus corresponded to 7200 cu. ft. The coal was a mixture of 40 per cent low volatile and 60 per cent high volatile coal, which would average about 30 per cent volatile. The total amount of heat lost in waste gases and radiation at this plant was less than 4½ per cent of the total heat in the coal.

One important use, namely, for power development in gas engines, has not received the attention in this country that it has in Europe. So far as information is available, the only large gas engine installation using coke-oven gas in this country is at Lebanon, Pa., where four 1200-hp. engines using gas from the Semet-Solvay plant there develop electrical power for operating the Cornwall Ore Banks. According to published data, gas engines aggregating over 200,000 hp. for operation with coke-oven gas has been installed in Europe by three of the principal builders since the year 1904. A guarantee of 1 hp. per hour with 27 cu. ft. of average gas is not considered out of the way, which would mean about 200 hp.-hr. per ton of coal, or for each modern coke-oven the capacity to produce 125 hp. continuously, as long as it is in operation. A battery of eighty ovens would yield 10,000 hp.

The actual recovery of benzol is a relatively simple matter. It is based upon the property of certain high-boiling oils to absorb the crude benzol vapors from the gas, and to yield them up again when heated to a temperature below their own boiling point. The oils employed for this washing are the so-called petroleum "straw" and tar creosote oils. English practice prefers a tar creosote oil distilling from 220 deg. C. to 250 deg. C., although heavier oils distilling from 250 deg. to 300 deg. are also used. All the American benzol plants use the petroleum straw oil because it is cheaper than coal-tar oils and the benzol can be more sharply separated from it in the type of continuous still used.

The washing of oven gas with oil for benzol is practically parallel to the washing with water to recover ammonia, the guiding principle being to bring the gas into intimate contact with a maximum surface of the cool washing liquid. The benzolized oil passes from the washer through a preliminary heater to the still, where the benzol vapors are driven off by a combination of direct and indirect steam. The exit oil is cooled and returned to the benzol washers, while the benzol vapors pass to the condenser and are delivered as light oil. This contains possibly 10 to 15 per cent toluol, and 45 to 55 per cent benzol, with small amounts of xylol and naphthalene. From the crude light oil the refined products are obtained by successive distillation and by treatment with the sulphuric acid and alkali. Benzol is usually made as 50 per cent, 90 per cent, and 100 per cent grades, the percentages referring to the amount that will distill over at 100 deg. C., not to actual purity. For pure benzol the specification requires that 100 per cent shall distill over within a range of 2 deg. C., within which range shall be the true boiling point of benzol.

Until recently there have been few gas works or coke-oven plants recovering cyanids from their gas in

this country. Late developments indicate, however, that several new plants are about to begin operations. Under normal market conditions there is probably little profit to be obtained from its recovery from coal gas.

The coal-tar industry in the United States has passed through two stages and is now entering upon a third epoch. In the first stage, from 1857 when tar was first distilled at Buffalo by Samuel Warren, until about the beginning of the present century, tar distilling necessarily followed "rule of thumb" methods and progressed in volume of material handled rather than in improvement of processes or development of new products and new markets. Great credit is due the pioneers in the industry for building up during this period a substantial business, particularly in the line of roofing material. They laid the foundations and at the same time outstripped in methods and in volume of business the roofing branch of the tar industry in all European countries. It is also important to note that during this epoch, in the year 1887, the H. W. Jayne Chemical Company, Philadelphia, was established for the production of naphthaline, refined carbolic acid, benzol and nitro-benzol. This was the beginning of the plant that in 1896 became the chemical department of The Barrett Company.

The second stage of the industry, comprising roughly the first decade of this century, was a period of engineering development attended by such progress along chemical lines as was necessary to the working out of largely increased production on the one hand, and more exacting demands from consumers on the other hand. The technical specification, as applied to paving, roofing and waterproofing materials, to creosote oil, to crude as well as to refined products, became an important factor. Laboratory control of products was inaugurated, requiring in many instances the working out of new methods for testing and analysis. In 1900 the Barrett company had, outside the chemical department, perhaps four or five chemists in its employ. In 1915 there were over fifty. During this decade and a half, large producers have had to spend much time and money in co-operative work on standards for methods and materials.

We are now entering into the third stage of development. The searchlight of newspaper and popular magazine attention has been thrown upon coal-tar, although it must be said that this naturally dark subject has not been highly illumined by the rays from that quarter. Coal-tar began to be regarded as a sort of Aladdin's lamp, and for many months it was no uncommon thing to receive inquiries for "50,000 gal. of tar a day" from respectable and previously conservative manufacturers of cast-iron pipe, sewing machines or porcelain bathtubs, who contemplated going into toluol at \$4.50 per gal. as a profitable side-line.

"The portion of tar that can be used in making synthetic dyes and chemicals is only 10 per cent of its whole composition. I cannot overemphasize the fact that the continued growth of the tar industry, and its ability to take care of the largely increased supplies that are already in sight, depend entirely upon the disposal, at profitable returns, of the two principal items that constitute the great bulk of the product of tar distillation, viz.: **pitch** and **creosote oil**.

The total United States production of coal-tar in 1915 was approximately 180,000,000 gal., of which 140,000,000 were from by-product ovens and 40,000,000 from gas works. We have, therefore, three distinct types of tar: first, that from horizontal gas retorts, which may be expected to gradually diminish in quan-

tity; second, that from by-product ovens, which it is estimated will reach 250,000,000 gal. in 1917; third, a much smaller but gradually increasing amount of vertical retort tar.

These three kinds of tar differ widely in characteristics. The difference may be roughly expressed by saying that horizontal or old-fashioned gas-works' tar is the heaviest, most viscous and contains a lower percentage of oils and more pitch. It also contains the highest percentage of suspended or "free" carbon—the portion of tar insoluble in benzol. Coke-oven tar occupies an intermediate position. It is usually lighter and contains more oils and less pitch than horizontal gas-works tar. Its free carbon content is lower. Vertical retort gas-works tar is lighter, less viscous and contains more oils and less pitch than coke-oven tar, and is also lower in suspended carbon. In order to meet specifications controlling the sale of products, it is generally necessary to combine two or more tars before distilling. Thus the problems of the tar distiller are rendered more complex by each new type of gas retort or coke-oven that is introduced, and by each change in coking time or temperature at existing plants.

The quality of tar may never be the controlling factor in deciding the type of oven or gas retort, or even in determining the heats and time of coking; nevertheless, some consideration of this phase may be worthy of the attention of coke-oven operators.

The reduction or disappearance of valuable constituents means, of course, that the tar is really worth less than before. In the past, such conditions have not influenced the price of tar. Doubtless the time will come when the real value of each tar, based on its composition, will affect the price.

There are at present about fifty distilling plants located in the United States. Many are naturally in the large cities, where the greatest demand exists for the road surfacing materials, paving pitch and roofing, that constitute the largest items of tonnage. Another reason for having tar-distilling plants located in large cities is the exacting service required in the delivery of road tars and paving pitch, in which hundreds of motor-driven tank trucks are engaged. Hence, freights from gas or coke-oven works are often 25 to 40 per cent of the value of the tar at shipping point.

The transportation, handling through plant, dehydration and mechanical features of tar distilling would require a separate paper. Over 1200 tank cars are now engaged in the transportation of tar and tar products, and on the Atlantic Coast there are about twenty barges of 25,000- to 300,000-gal. capacity. At one of the larger plants there are fifty storage tanks of 1000- to 20,000-bbl. capacity.

There are few if any proper uses for crude tar, both by reason of its varying character and because the presence of water and ammonia is objectionable in practically all cases. However, crude tar can be successfully burned in the same manner as heavy petroleum distillates and residues. At this point it may be well to say that tar itself as well as any of the crude fractions obtained from it, can replace petroleum fuel oils in steam plants, metallurgical furnaces, etc., whenever the relative value of the products makes burning a good economic policy. Tar oils have been successfully used in engines of the Diesel type in this country and abroad. In Germany tar oils are apparently the preferred fuel for these engines. Coke-oven tars average about 16,500 B.t.u. value, and the heavy distillates 17,000.

Pitch comprises from 50 to 80 per cent of the tar,

depending on the character of tar and the hardness of the pitch. Its uses are varied. Long experience in some fields and scientific research in others have determined what physical and chemical properties are desirable in pitches for each important use. In order to produce pitch meeting these requirements the tar distiller has especially to study, select and combine tars of different quality.

It is in the development of soft and medium pitches that the American tar distiller has far surpassed the achievements of his European contemporaries. We have extended the use of pitch into much wider fields, and in addition to that we have devoted infinitely more care to the production of pitches meeting the special requirements of each purpose. Large sums of money have been expended, not only on advertising such uses for pitch as the specification roof and road tar, but on the technical development of these products, and on educating the architects and engineers upon whose decision the choice of materials depends. It was frankly admitted by the delegates from England, France and Germany at the International Road Congress in London in 1913, that in technical work on the use of bituminous materials in road construction, American chemists and engineers were far in the lead.

The tremendous increase in the output of coal-tar from new and enlarged by-product coke-oven plants has made it imperative to find new uses for pitch. One rather promising outlet for very hard pitch is as pulverized fuel, where, in some cases, for metallurgical work, it can compete advantageously with fuel oil. Hard pitch normally contains less than one-half of 1 per cent ash and only about one-third to one-half of 1 per cent sulphur. For these reasons it can be used where pulverized coal would be out of the question on account of much higher ash and sulphur content. Work on another pitch outlet was started by our engineers nearly a year and a half ago, in the line of mixing with coke breeze or non-coking coals to supply the cementing properties necessary for satisfactory coking. It is very interesting to note, by frequent references in the English gas journals within the past few months, that the surplus of pitch in England has caused experiments to be made there along this line.

Conclusions

(1) The by-product coke-oven industry is entering a period of rapid development. The by-product industries must expand to keep pace with it.

(2) This expansion must take place on lines adapted to our own conditions and to the large volume of materials involved. We may learn from foreign experience, but we must not be content to copy their methods.

(3) The great outlet for ammonia is in agriculture, in which direction there seems ample room for development, though it may come slowly and need fostering.

(4) The future field for gas is in an increased use for general city and industrial service, made possible by more widely extended distribution systems and by replacement of natural gas shortages, also in generating power by means of gas engines.

(5) There is an ample supply of benzol, toluol and homologues now recovered from our present domestic consumption of solvents, chemical derivatives and explosives. After the present abnormal conditions are past, the surplus will find ready use as motor fuel.

(6) New uses for tar must be found for an increased production of 100 per cent within two or three years, unless it is to be used as fuel. Refined derivatives, including phenol, cresols, naphthaline and intermediates, will be produced in sufficient amount to meet the

demands of the color, drug and chemical manufacturers. The degree of development in this direction depends on the action of the Government with regard to protective measures and upon the co-operative effort of the industries involved.

The increased amount of cresote oil will tend to keep the price at such a level that European producers will seek to find outlets at home for their surplus.

The outlook for pitch is exceedingly problematical. Although new uses may be confidently looked for, it seems inevitable that a large portion of pitch must find its outlet in the fuel field.

(7) The by-product coke-oven, besides being an integral part of our steel industries, is our main source of benzol, toluol and phenol for munitions and the wide range of chemicals of scarcely less importance. It is also our only operating native source of combined nitrogen for nitric acid, and the only possible one outside of the processes for fixing atmospheric nitrogen.

Chemistry of Portland Cement

The manufacture of Portland cement has grown so that the present output is about 100 million barrels per year. The mechanical part of the manufacture has undergone many changes. An article by George P. Diekmann in the *Journal of the American Society of Mechanical Engineers*, May, 1916, gives an interesting review of the chemistry of Portland cement.

The chemical process is carried out in the same way as laid down by the investigations of Fuchs and Vicat, two scientists of the early part of last century. Of course, the advanced knowledge of chemistry and the researches of eminent men have given us more and truer knowledge of the chemical composition of cement, and in order to throw more light and awaken more interest in research, a prize has been offered by the Prussian Government for the best essay on the constitution and hardening process of hydraulic cements, and efforts are renewed to solve this much disputed problem.

Portland cement is a hydraulic cementing material with not less than 1.7 parts by weight of lime to 1 part of soluble silica plus alumina and iron. The lime necessary to produce Portland cement is found as limestone called calcareous matter, and the silica, alumina and iron are found in clay, called silicious matter; the calcareous and silicious materials are mixed in proper proportions and burned to incipient fusion at a temperature of about 2600 to 2800 deg. Fahr. and the resulting clinker ground, to which 3 per cent of gypsum is added to regulate the setting time. Portland cement should not have more than 1.75 per cent sulphuric acid, which is equivalent to about 3 per cent calcium sulphate or gypsum, and not more than 4 per cent magnesia, although these specifications vary in different countries.

Chemically Portland cement is a salt composed of acid and basic constituents of such a composition that none of the bases are unsaturated. The main elements are silica, alumina and iron, known as the acids, and the lime and the magnesia are known as the bases. When limestone and clay have been intimately mixed and ground together to an impalpable powder, this then represents the mechanical mixture of acid and basic constituents, or what is the same, the silicious and calcareous materials. In subjecting this mechanical mixture of limestone and clay to the influence of heat at about 2600 to 2800 deg. Fahr., the mechanical mixture is converted into a chemical compound, and limestone and clay exist no longer in their original form, but are converted into an entirely new

chemical compound, a clinker, called tri-calcium silicate.

Various theories are advanced on the chemical composition of cement. According to Zulkowsky, there are existing two isomorphous compounds of the di-calcium silicate, the non-ortho active modification, the ortho silicates, the active modification and the basic meta-silicates. The meta-silicate is considered a strong hydraulic, having hardening properties in contact with water. The ortho silicate has no hydraulic properties and disintegrates. In other words, silica, lime, alumina and iron must be present in such a ratio that certain chemical action is produced.

According to Le Chatelier, whose work has long been considered the modern theory on cement, cement is a tri-calcium silicate. Professor Michaelis recently advanced the colloid theory, which might give an entirely new view on the constituents of cements. Clifford Richardson made a very thorough microscopic examination of cement clinker and his studies are very interesting. According to these theories, the total basic constituents of any cement expressed in equivalents should not be greater than three times the total acid constituents expressed in equivalents. According to Michaelis, the composition of the cement should be such that the ratio of the acid constituents to the basic constituents shall be from 1.8 to 2.2 times larger by weight. This formula is the one most used and enables the composition to be judged from the analysis very quickly.

In Portland cement each element performs a certain function, and therefore the elements should have a certain ratio to each other, as follows:

Lime to silica... 2.8:1 minimum; 3.2:1 maximum;
Alumina to iron... 2.5:1 minimum; 3.5:1 maximum;
Iron to alumina... 2.0:1 minimum; 3.0:1 maximum.

The chemical composition of Portland cement is very uniform and is usually as follows: silica, from 20 to 23 per cent; alumina, from 5 to 8.5 per cent; iron oxide, from 1 to 4 per cent; lime, from 60 to 64 per cent; magnesia, from 0.5 to 3.5 per cent, and sulphuric acid, from 1.5 to 2.5 per cent.

There are certain formulae for the calculation of the proper proportion of each raw material in relation to the others according to chemical composition and physical nature. One of the most convenient which is used is a formula according to C. Shoch by which the desired ratio can be determined according to the analysis of the materials which are calculated on the total silicates containing silica, alumina and iron. However, no matter what formula might be chosen, the Portland cement raw mixture contains usually from 42 to 43 per cent lime and 20 to 21 per cent silica, or a ratio of 2:1; this may sometimes be as low as 1.8:1 and as high as 2.2:1.

Portland cement contains usually from 5 to 8 per cent alumina. With an increased amount of alumina the cement becomes quicker setting, and if the alumina content reaches about 9 per cent, the cement becomes very quick setting, due to the formation of a tri-calcium aluminate. If alumina is present in quantities exceeding a certain limit it is considered detrimental, as it not only produces a quick-setting cement, but has a greater expansion power, especially if hardening takes place in sea water or water containing alkaline matter. The aluminates are parts of a cement which are most easily acted upon by certain salts contained in sea water, forming water soluble compounds which in time destroy the cement.

Iron in a cement combines with lime and acts as flux similar to alumina in lowering the fusing point

between the acid and basic constituents. Iron will give cement a darker color. Alumina might be replaced by iron giving an excellent cement for marine work. In fact, there are now manufactured in Germany iron Portland cements which are claimed to be superior to ordinary Portland cements for sea water construction.

The effect of magnesia on cement is still a matter of investigation, but all agree that a large amount of magnesia is detrimental to cement. It is of so much more danger than other constituents as the expansive power of magnesia will occur long after setting. The general specifications call for not more than 4 per cent magnesia, while the German specifications allow a limit of 5 per cent. Candelot in his investigation stated that magnesia produces the same effect as free lime.

In recent years the many accidents occurring in construction where magnesia cements have been used have drawn attention to this question. Magnesia cements give very good results in tests, and masonry made with these cements shows desirable solidity sometimes during several years, but after a certain time swelling begins to manifest itself, and with such intensity that nothing can resist it. Candelot stated that a rod of magnesia cement 1 m. long was found to elongate 26 mm. in three years. Dyckerhoff stated, after very thorough research work in which he studied the effects of magnesia, that when magnesia is added to the raw material or substituted for an equivalent portion of lime, it causes a decrease in strength in the resulting cement if present in a proportion greater than 4 per cent. Cracking occurs only with 8 per cent magnesia or more.

It is known that magnesia compounds become hydrated much more slowly than calcium compounds, and this is evident as although concrete consisting of calcium silicate and aluminate will harden and set in a proper manner, cement containing magnesia either in combined form or as free magnesia will, due to the slow hydration after setting, undergo changes and molecular movements, causing expansion and cracking. The natural cements contain usually from 16 to 22 per cent magnesia, but here the magnesia has no injurious effects as in Portland cement. The trouble lays in the burning, as while Portland cement raw mixture is burned at a high temperature, in effect incipient fusion, forming a very dense clinker, in a natural cement mixture only a moderate heat is applied to drive off the carbon dioxide. The resulting clinker is soft and the magnesia is hydrated here very quickly; the hard clinker obtained with this process is picked out and not used.

The amount of sulphuric acid in a Portland cement should not exceed 1.75 per cent, but according to the German specifications 2.5 per cent is allowed. The presence of sulphuric acid in a cement is due to the addition of calcium sulphate, which is added in the form of rock gypsum or burned plaster before or after grinding the clinker. Portland cement clinker is more or less quick-setting, and, in order to retard or regulate the setting time, a small amount of gypsum is added. The amount depends on the composition of the raw materials—usually from 2.5 to 3 per cent is added.

Portland cement clinker usually contains about 0.1 to 0.4 per cent of sulphuric acid due to the sulphates in the raw materials, which are mostly converted by the high heat to volatile acid and driven off. A small amount of this acid is also due to the ash from the coal, which becomes part of the cement. If the burning or fusion takes place in a reducing atmos-

where, the sulphates will be converted to sulphides, forming mostly iron and calcium sulphides, which will again be oxidized to sulphates. The small amount of calcium sulphate added to cement retards the setting time.

When cement is mixed with water chemical action takes place at once, according to Le Chatelier. The hardening process is due to a deposit of inter-locking crystals from a super-saturated solution, part of the water entering into chemical combination. There are two distinct chemical actions which take place, the setting or hydration and crystallization or hardening process. The process of setting is due to the formation of aluminates of calcium, developing a certain degree of heat, but the addition of calcium sulphate prevents quick hydration by forming sulphate of aluminate of calcium, which hydrates very slowly without developing heat.

Along with the hydration the hardening process is beginning very slowly. The tri-calcium silicate is decomposed by the action of water to mono-calcium hydrate. The process of crystallization begins very slowly, and as time goes on the crystals become more closely interlaced, forming a denser body and attaining a stone-like character, called hydraulic character, and it is this process which makes Portland cement such a high-grade hydraulic mortar. If once formed, no action of the elements can disturb its increasing crystallization, and as Portland cement is the binding medium in concrete, any suitable aggregate will become embodied and form an unseparable bond of natural stone.

Portland cement develops in the hardening process about 40 per cent of its total strength in the first 24 hr., 60 to 70 per cent in 7 days, 80 to 85 per cent in about 30 days, and it will attain its maximum strength in about 6 to 12 months, depending on the season of the year. This explains why a cement of 24 hr. is not as strong as at 7 days, and at 7 days not as strong as at 28 days.

Science Linked with Industry

Presidential address delivered at the dedication of the new Massachusetts Institute of Technology in Cambridge, Mass., June 14, 1916.

BY RICHARD C. MACLAURIN

We are here to dedicate a noble group of buildings to a noble purpose. The buildings speak for themselves. They will form an enduring monument to the skill of the architect, the capacity of the engineers of construction, the devotion of the faculty that has planned so much of their detail, and the splendid public spirit of the anonymous benefactor whose gift they are. That gift has won admiration not only for its munificence but for the unostentatious manner in which it was made and for the patriotic purpose to which it has been devoted. It will have far-reaching consequences for the country at large, for its aim is to strengthen American industry at the base by fixing it firmly on the solid rock of science.

How striking is the change that has come over the world in its view of the relation between science and industry! Each is of venerable antiquity, for while science in its growth has gaged the intellectual development of mankind from the beginning, its application to practical affairs is coeval with the manifestation of the scientific spirit. In the early days, however, the two things, science and practice, rarely, if ever, went together, and were often regarded as antagonistic. To-day we are far removed, indeed, from the aristocratic contempt for practical things so freely expressed by Plato and even by Archimedes

himself. No such feeling has been manifested by the great modern masters of science such as Newton, Pasteur, Faraday, or Kelvin, although a trace of it may be found occasionally among the lesser lights.

We do well to rejoice in this change of heart and outlook, a change that means so much to the world; but in so doing we should not fail to recognize our debt to the past. So we have clothed these laboratories in the forms of classic art, and have done this not merely that students may be influenced by the beauty of their simplicity, but that they may observe how well that art adopts itself to thoroughly modern needs. Thus may they have a practical proof of the error of supposing that old things are of necessity useless and a forcible reminder that much that is most potent in our life to-day has its roots deep in the past. For a somewhat similar reason we have inscribed on the walls of these buildings the names of the imperishable dead in the hope that they may inspire our students with the thought that each succeeding age inherits the intellectual wealth of all that has gone before and fails in its duty unless it makes it its high vocation to hand on the heritage that it has received and to enrich that heritage by contributions of its own.

But although we are not unmindful of what we owe to those who have preceded us, our look must be ever ahead. The opportunity immediately before us is alluring in the extreme. The greatest war in history will inevitably mark the end of one era and the beginning of a new. For some time before the war, but particularly during its progress, the world has been given an impressive demonstration that the methods and the means of science are indispensable in many a practical field. In the new era that is about to dawn we must take our share in making the dominance of the scientific spirit pre-eminent in every phase of industry and practice. In that era no half measures will avail. We must get it into the minds of the rising generation that for success nothing must be done haphazard or by "rule of thumb." All must be orderly and logically planned, resting ever on the solid ground of fact, and industry like science must be matter not of expedients nor of guesses, but of laws.

Our prosperity as a nation, perhaps even our very existence, must depend on the extent to which we assimilate this doctrine. In the great industrial struggle that will follow the present war, and that will go on indefinitely, many of the advantages of this country will be offset by serious disadvantages. If victory be ours, it will be no easy victory, but assuredly we have a splendid opportunity of success if only we organize our industries on a scientific basis. We must train men in the methods of science and make the proper use of these technically trained men when we have got them. This—the adequate supply of properly trained men—is the cardinal doctrine of industrial preparedness recognized by thinking men to-day as one of the greatest necessities of the times.

The opportunity for this country to take and keep the lead industrially is constantly before us in these days, but there is another opportunity seldom, if ever, mentioned, that is in some respects even greater. The center of intellectual achievements in the world has passed in turn from Egypt and Babylonia, to Greece, to Alexandria, to Constantinople and to western Europe. Is it to cross the Atlantic? If this be so, the intellectual leadership must accord with the genius of our people for practical affairs. That genius will inevitably show itself chiefly in industrial pursuits and industry will continue to attract a large proportion of the best minds of the country. Hence we must

have industry linked with science, not merely for the benefit of industry but for the sake of science. Of course, our American science will never grow as it should if it is cramped by a short-sighted policy as to what is useful. But if the value of science to industry be generally appreciated, science will be free to expand in any direction, and if it be pursued with the same energy and intellectual power that have been applied to business, there is no reason why America should not become the intellectual leader of the world.

Here is a great hope and a great national opportunity. The problems that it presents are not local and must be looked at from no merely local point of view. They demand the co-operation of all, and as a step toward that great end, Harvard and Technology, each national in its scope and influence, are here combining for the common good.

And so, in the presence of representatives of other learned societies from all parts of this country and from abroad, inspired by their sympathy and their achievements, we dedicate these buildings to the great cause of science, linked with industry.

Synopsis of Recent Chemical and Metallurgical Literature

Storage Batteries

Theory of the Lead Accumulator.—Plante and Faure considered that when a lead storage cell is being discharged, the PbO , plate changes to PbO and the Pb plate to PbO so that the lead accumulator would be simply what we now call an "oxygen-lift" cell. However, this theory was abandoned at an early date in favor of the double sulphate theory, according to which during a discharge the PbO , plate as well as the Pb plate are changed to PbSO_4 . While this theory has been widely accepted, it has also been opposed by some, and the latest modification proposed is that of CH. FÉRY in a French Physical Society paper (*La Revue Elec.*, June 2, 1916). On the basis of experiments carried out by him jointly with M. Fournier, he proposes the following theory. The "negative" plate only behaves as assumed, being Pb at the end of the charge and PbSO_4 at the end of the discharge. On the other hand, it is claimed that the "positive" plate at the end of the charge is Pb_2O_3 and PbO , at the end of the discharge, so that the total reaction during discharge would be given by the equation $\text{Pb}_2\text{O}_3 + \text{H}_2\text{SO}_4 + \text{Pb} = 3 \text{PbO}_2 + \text{H}_2\text{O} + \text{PbSO}_4$. The change from PbO_2 to PbO , is endothermic and absorbs 9000 calories, while the change from PbO to PbO_2 sets free 12,000 calories.

Cement

Properties of Portland Cement.—A study of the compounds existing in Portland cement is very important to the cement industry. Such work has been undertaken by the Geophysical Laboratory of the Carnegie Institution in Washington, and described by GEORGE A. RANKIN, in the *Journal of the Franklin Institute* for June, 1916.

Ninety per cent of an average Portland cement consists of the three oxides, CaO , Al_2O_3 , and SiO_2 . It is to be expected, therefore, that its properties are due mainly to the presence of the above three components, and that the relatively small admixture of the other oxides exerts at most a wholly secondary influence. It has been shown that good Portland cement can be made from three pure oxides, lime, alumina, and silica, in the proper proportions.

Now, ordinary chemical methods enable us to ascertain the aggregate proportion of each oxide present,

but they yield us no information as to the manner in which these oxides are combined with one another—in other words, as to the substances which actually are present in the clinker and are responsible for its characteristic properties. The determination of this question is very important, for this reason; that, until we know what these substances actually are, we cannot hope to improve the quality in any desired direction, except by cut-and-try methods; and it is generally recognized that such empirical methods are much less certain, and take a vastly longer time to reach the goal, than methods based on a real knowledge of the factors in the problem. The determination of this question has been the object of a very large number of investigations; but the experimental basis of most of this work has been altogether insufficient to decide the several questions at issue. There has been in general a failure to realize the fact that a system so complicated as this can be unraveled only by proceeding systematically, using as a guide the principle known as the phase rule and establishing definite criteria for the recognition of the several substances which occur.

Cement clinker is a mixture of substances of very similar properties, and is, moreover, exceedingly fine grained, as a consequence of which it is a matter of some difficulty to make quantitative determinations of the constituents; but this difficulty can be surmounted by studying separately each of the presumable constituents of the clinker and determining definite values of certain properties which serve to characterize it and to distinguish it from other possible constituents. Accordingly the first problem is to isolate and determine all the possible compounds of lime, alumina, and silica which we may expect to find in Portland cement clinker, to establish their relations at high temperatures, and to ascertain their optical characteristics which constitute the most convenient and satisfactory criterion of the identity of the several substances.

In order to work out this system completely it proved necessary to investigate about 1,000 different mixtures of these three oxides and to make about 7000 heat treatments and microscopical examinations of the resultant products. Each such mixture, which was always made up of especially pure materials, was alternately fused and ground to a fine powder, the fusions being made in a platinum crucible to avoid contamination, in order to obtain a thoroughly-combined product. Each of these products was heated in an electric furnace, the temperature of which was carefully controlled and measured, until all changes had ceased, when it was quickly chilled; and the resultant material was subjected to a complete optical study. This procedure, carried out systematically, enables one to determine the crystalline phases present at temperatures ranging from that at which melting begins to that at which the charge is completely melted; and thus to ascertain the melting temperature and optical properties of all compounds of lime, alumina, and silica which form when any mixture of these three oxides is heated.

The results are summarized as follows: The value of Portland cement depends upon the fact that when finely powdered and mixed with water it forms a hard mass; and the strength and permanence of this mass depend upon the constituents of the cement. The major constituents are tricalcic silicate, dicalcic silicate, and tricalcic aluminate. Of these constituents, the compound tricalcic silicate is the one which hardens and develops the greatest strength within a reasonable time. This most important constituent, which is the one formed with the greatest difficulty, makes up only 30 to 35 per cent of an average normal Portland cement. It may be said, therefore, that the essential process for the manufacture of Portland cement is the formation of

this compound, and that any improvement in this process yielding an increased percentage of tricalcic silicate will increase the cementing value of Portland cement. In order to determine the most economical process for producing tricalcic silicate in the highest percentages, it will be necessary to study the rate of formation of this compound in a series of mixtures of various substances; this, in turn, necessitates the determination of the equilibrium relations of tricalcic silicate at high temperatures in such mixtures. Such a procedure will lead sooner to the discovery of the optimum composition in various cases and for various purposes than the empirical, cut-and-try methods which hitherto have been the only methods tried.

Fire Brick

Effect of Compression Loads on Fire Brick.—Some interesting experiments on the effect of compressive loads in reducing the temperature at which fire brick will soften, are described in the *London Engineer*, June 9, 1916. The experiments were performed by Dr. J. W. MELLOR and Lieut. B. J. MOORE and described by them in a paper presented to the English Ceramic Society of which the above is an abstract.

The apparatus consisted of a cylindrical electric furnace with an inner core of refractory material, sur-

ponential constant. The temperature can be expressed in degrees Centigrade or else in terms of Seger cones. To conform with industrial conventions the latter method has been followed.

(4) The more siliceous the clay, the less the difference between the squatting temperature with or without a load; and, in most cases, the more nearly the composition of the fire-clay approaches that of china-clay, the greater the difference between the squatting temperatures with and without a load. The squatting temperature of china-clay is lowered approximately one cone for every increase of 5½ lb. per square inch in the load.

Iron and Steel

Relation Between Cutting Efficiency and Hardness Tests of Tool Steels.—In a paper presented at the annual meeting of the Iron and Steel Institute in London, Professor J. O. ARNOLD, discusses the lathe efficiency of tool steels in its relation to hardness tests. He states that in recent papers read before the Institute there has been a tendency to regard the Brinell and scleroscope numbers as an approximate measurement of the cutting efficiencies in the lathe. This he states is incorrect as there is no relation between Brinell hardness and cutting efficiency. The efficiency de-

TABLE I

Note.—The Brinell and scleroscope hardnesses were taken as near as possible to the hardened cutting edges of the various tools.

*It will be seen that with both types of steel the maximum efficiency is obtained on the second grindings of all seven tools.

*Duplicate test 629.

*Throughout these tests the cutting edge of the tool was red-hot at the breakdown points, and indeed for about five minutes previous to breaking down.

rounded by granular graphite, which is retained in place by a thick fire-clay cylinder, and this in turn surrounded by an iron casing. Iron electrodes are fastened in connection with the graphite. The clay to be tested is molded in the form of a cylinder and placed on a block which forms the bottom of the furnace. By a lever arrangement something like a piston rod through the top of the furnace different weights can be supplied to the clay to be tested, and the temperature at which the piece fails is observed.

The conclusions from the tests are as follows:

(1) The squatting temperature of fire-clays is reduced by a compressive load. The greater the load, the lower the squatting temperature.

(2) The decrease in the squatting temperature with unit increase of load is directly proportional to the squatting temperature, and equal to k times the squatting temperature.

(3) The relation between the squatting temperature T and the load w , expressed in pounds per square inch, is given by the expression

$$T = C e^{kw},$$

where C represents the squatting temperature of the briquette without a load, k is a constant the numerical value of which is dependent upon the particular clay, on the mode of manufacture of the briquettes, on the grain-size of the clay, etc., and e is the regular ex-

pends almost entirely on the thermal stability of the simple or compound hardenites in the hardness steel. Table I shows tests made on two different types of steel.

Influence of Carbon and Manganese Upon the Corrosion of Iron and Steel.—Some interesting and valuable results on the effect of various amounts of carbon and manganese on the corrosive properties of iron and steel have been obtained in experiments carried out by Sir ROBERT HADFIELD and J. NEWTON FRIEND. The results were described in a paper presented at the annual meeting of the Iron and Steel Institute in London. The authors state that there has been much conflicting information in regard to the effect of manganese in steel, and no conclusive evidence has been advanced. The present research was undertaken with a view to throwing further light upon this intricate problem. Of late years it has been repeatedly emphasized that different corroding media exert very different effects upon iron and steel, no one metal resisting all kinds of corrosion equally well. The authors considered it essential to test the steels in a variety of ways, viz., by exposure successively to tap water; sea water; alternate wet and dry; a process closely corresponding to a changing climate; and by exposure to 0.1 and 0.5 per cent sulphuric acid.

The results are briefly as follows:

The addition of carbon from 0.03 to 1.63 per cent to

pure iron containing less than 0.2 per cent of manganese, results in—(a) A steadily increasing rate of corrosion both in tap-water and in sea-water, slight maxima being observed in the neighborhood of 0.6 to 0.8 per cent carbon. (b) An initial fall in corrosion, with a rapid rise to a maximum with 1.05 per cent carbon in the wet and dry tests. (c) A rapid rise in corrosion to a maximum with 0.8 per cent carbon when exposed to the action of dilute sulphuric acid. Clearly there is some difference of behavior towards all the corroding media in the case of the steels in the neighborhood of the eutectic composition, the specimens showing either a tendency toward increased corrosion or else a most decided increase in corrosion.

The addition of 0.7 per cent manganese to the above steels first results in a very slightly increased corrosion in tap-water, sea-water, and in wet and dry tests, with a carbon content up to about 0.4 to 0.5 per cent. From this point upwards the manganese, generally speaking, affords a slight protection, which is very decided in the wet and dry tests, but is not invariable in the sea-water tests.

A second result of the addition of 0.7 per cent manganese to the above steels is an enormously increased corrosion in dilute sulphuric acid. This is particularly important, since in commercial steels the manganese content frequently ranges from 0.2 to 0.7 per cent, and it is evident that the latter are absolutely unsuited for exposure to acidified corroding media. Just as in the experiments with the steels of 0.2 per cent manganese content, a point of maximum corrosion is observed; but this always occurs with a smaller carbon content in the steels with 0.7 per cent manganese.

By increasing the manganese content to 2 per cent upwards—(a) The corrodibility in neutral solutions is greatly decreased, particularly when the carbon content exceeds 0.5 per cent. (b) The corrodibility in dilute sulphuric acid is greatly enhanced.

The authors emphasize the fact that they have confined themselves exclusively to a consideration of the actual results obtained with the steels without in any way considering the theoretical reasons for the observed phenomena.

Copper and Lead

Decomposition and Reduction of Lead Sulphate.—

A contribution to our knowledge of the behavior of lead sulphate at elevated temperatures is offered by W. MOSTOWITSCH, of Tomak, Russia, in the May *Bulletin* of the American Institute of Mining Engineers. In studying the decomposition of lead sulphate by heat, the author found that partial dissociation, with evolution of SO_2 , begins at 800 deg. C.; that the speed of dissolution is slow up to 950 deg. and quick when the temperature is raised above 950 deg.; that fusion, which occurs between 950 deg. and 1000 deg., takes place only after partial decomposition of normal PbSO_4 . Up to 1000 deg. C. no volatilization of PbO was observed, but above that temperature it was very noticeable, forming a sublimate on the boat.

In the presence of silica the dissociation temperature of PbSO_4 is not lowered. It is marked at 950 deg. and increases as the temperature is raised. The decomposing effect of silica is not proportional with the SiO_2 content, but rather the reverse holds true. Decomposition appears to be governed by the viscosity of the lead silicate which is formed; in the bi- and trisilicate mixtures viscous slag envelopes PbSO_4 and retards action. The most rapid decomposition accompanied by the lowest loss of lead by volatilization is found with a silication lying between the singulo- and the bisilicate and containing from 10 to 15 per cent SiO_2 .

The reduction of PbSO_4 by CO begins at 600 deg. C.;

the salt loses in weight and becomes dark; SO_2 is set free. At 630 deg. C. there are visible pellets of lead, and the loss in weight of 21.58 per cent exceeds the oxygen content, which is 21.11 per cent. All the phenomena prove that a reaction between undecomposed PbSO_4 and reduced PbS is taking place according to the two equations: $\text{PbSO}_4 + \text{PbS} = 2\text{Pb} + 2\text{SO}_2$ and $3\text{PbSO}_4 + \text{PbS} = 4\text{PbO} + 4\text{SO}_2$.

With carbon the reduction, which begins at 550 deg. C., is accompanied by the liberation of SO_2 . At 630 deg. the reduction proceeds more quickly than at 550 deg., the loss in weight is larger, and pellets of metallic lead are seen; the PbSO_4 has been largely changed to PbS. At 700 deg. the reduction to PbS and Pb is completed.

A comparison of the effects of the two reducing agents shows that CO begins to act at 600 deg. C., and carbon at 550 deg.; that the reducing power is increased with the temperature when CO acts more powerfully within the given limits than carbon does, for example, at 630 deg. the CO reduced 74.4 per cent and C only 36.98 per cent of the PbSO_4 .

In applying the foregoing results to reduction in the blast furnace, we have to consider the reducing agents and the temperatures. In the blast furnace the reducing agents are the solid carbon of the coke and the gaseous CO of the ascending gas current which travels at a rate of about 22 ft. per second. The furnace charge receives from 12 to 15 per cent coke. The gases passing from the throat of the furnace at a temperature of from 100 deg. to 150 deg. C. contain CO_2 15 to 21, CO 5.4 to 11.0, and oxygen 0.4 to 1.0 per cent by volume; usually the ratio of CO_2 : CO is as 3 : 1. The reduction of PbSO_4 by carbon and CO is energetic at 600 deg. C., and with it takes place the action of PbSO_4 upon PbS; both reactions occur at a temperature below that of decomposition of PbSO_4 by heat alone. The elimination of sulphur which may amount to from 25 to 40 per cent is therefore largely due to the action of PbSO_4 upon PbS in the upper part of the furnace. An advantage in using blast-roasted lead ore as regards elimination of sulphur lies in the fact that the sulphur is present mainly as sulphate which is readily eliminated as SO_2 and does not increase the matte-fall. The CaO of the limestone added to the blast-roasting charge (CaCO_3 = per cent S + 2 per cent) is converted into CaSO_4 , and this is either reduced at 800 deg. C. to CaS and enters the slag as sulphide, or it is dissociated at 1000 deg. C. by SiO_2 and enters the slag as silicate. The SO_2 of CaSO_4 in blast-roasted ore has therefore as little influence upon the matte-fall as has the SO_2 of PbSO_4 . Slags running high in FeO have been found to hold in solution as much as 7 per cent S; thus two slags made at Stolberg, Rhenish Prussia, with 55 and 38 per cent FeO contained 7.4 and 3.7 per cent S.

The flowing temperature of copper and copper-nickel mattes has been investigated by G. A. GUESS and F. E. LATHE to determine whether copper-nickel mattes might have a lower flowing temperature than copper mattes, and thus aid in accounting for the difficulty thus far experienced in pyritically smelting copper-nickel ores. The results are offered to the American Institute of Mining Engineers for presentation at the Arizona meeting this fall. Both laboratory and commercial mattes were investigated, the former being formed by fusing mixtures of white metal from copper converters and copper-nickel converters with varying amounts of iron sulphide.

The results of the experiments did not show as great a difference in flowing temperature between copper and copper-nickel mattes as was expected. The latter appear to have a flowing temperature from 30 to 50 deg. below copper mattes of the grade usually in blast-fur-

nace work. This slight difference in temperature is not regarded as sufficient to explain the failure in pyritic smelting due to a too early liquation of copper-nickel matte in the furnace. The paper gives tables and curves showing the differences in temperature observed for both copper and copper-nickel mattes prepared in the laboratory and secured from operating furnaces.

Recent Chemical and Metallurgical Patents

Gasoline

Gasoline and Other Volatile Hydrocarbons from Petroleum Residues.—A patent issued to CHARLES S. PALMER of Upper Montclair, N. J., on a process of treating petroleum residues to obtain volatile products, has for its essential feature the use of considerable pressure. The original application was filed on March 2, 1907.

The process consists in treating material such as "Florence," "Boulder," "Wyoming," "California," or "Louisiana" pitches or residues which are non-volatile below 300 deg. C. The residues are first melted in a steam-jacketed kettle, then delivered to a digester in which they are heated. During this treatment which occupies only a few minutes, the pressure gradually increases with the temperature, until a pressure of about 130 lb. per sq. in. is reached. There is then a sudden conversion of the materials present into more volatile compounds, which causes a rapid increase in the pressure without any substantial temperature increase. Apparently endothermic reactions take place which use up the heat as it is supplied.

The digester is connected to a still by a pipe line in which is a check valve which allows vapors to pass over above a certain pressure. The vapors from the digester are collected in the still and distilled separately from the undecomposed residues remaining in the digester. The fractional distillation of the collected volatile products yielded fractions as follows in actual tests: Up to 100 deg. C., about 5 per cent; 100 to 150 deg. C., 10 to 20 per cent; 150 to 200 deg. C., 10 to 20 per cent; 200 to 250 deg. C., 20 to 30 per cent; 250 to 300 deg. C., 10 per cent.

As illustrative of the effect of pressure it is stated that at 200 to 325 deg. C. and 60 to 90 lbs. pressure only 25 to 35 per cent of volatile products are obtained. With the same temperature limits and 100 to 150 lb. pressure, 50 to 75 per cent volatile products are obtained. At pressures ranging from 150 lb. up to 300 or 400 lb., 75 to 90 per cent volatile products are obtained. The first claim of the patent is as follows: "The process of treating petroleum residues of the paraffin series to increase the yield of volatile compounds above that normally obtainable therefrom, which consists in digesting the same in a confined space under a pressure in excess of four atmospheres and not exceeding 400 lb. per sq. in., said pressure being principally autogenous, and at a temperature in excess of 200 deg. C., for a time sufficiently long to induce transformation of the major portion of said materials treated into more volatile products, said temperature being below that point at which sufficient carbonization occurs to substantially interfere with such transformation, and said digesting being conducted with the treated materials being continually subjected to the pressure throughout the said digesting period of the evolved volatilized compounds undiluted by added aqueous vapors." (1,187,380, June 13, 1916.)

Electrolytic Processes

Process of Making Formic Acid.—A process of making formates and formic acid by the action of an

alkali amalgam on an aqueous solution saturated with carbonic acid gas, is patented by MOOSHUGH VAYGOUNY, of Berkeley, Cal., and assigned to the Royal Baking Powder Co. The process can be readily understood by references to the illustration, Fig. 1. A is a suitable container of non-conducting material, having on the bottom a layer of mercury B. Another vessel C, open at both ends, dips into the mercury B. An

FIG. 1—FORMIC ACID CELL

anode F of platinum, and a cathode G, connected with the mercury, are provided. A strong solution of potassium hydroxide is placed in the space D, and water is placed in the inside space E. Carbonic acid is introduced into the water in E by pipes J, and the solution is stirred by stirrer H.

As a direct current is passed from F to B, an amalgam will form in the mercury. By diffusion, assisted mechanically by stirrer H, or by rocking the cell, this amalgam is caused to travel to chamber E. Here reactions take place which form bicarbonate and formate. Potassium hydrate and hydrogen are first formed, the hydrate then combining with the carbonic acid to form bicarbonate and the hydrogen reducing the carboxyl grouping to the formate grouping. The temperature is kept below 40 deg. C., and the solution is allowed to become concentrated enough in formate so that the bicarbonate will be practically insoluble, thus effecting a separation of these two. The formate solution may be evaporated and crystallized and the formate worked up into formic acid. (1,185,028, May 30, 1916.)

Electrolytic Preparation of Tartaric Acids.—An electrolytic process of making tartaric acids from gly-

FIG. 2 ELECTROLYTIC CELL FOR TARTARIC ACID

oxylic acid or glyoxalates is patented by MOOSHUGH VAYGOUNY, of Berkeley, Cal., and assigned to the Royal Baking Powder Company. The process is carried out in a cell made of wood or other non-conducting mate-

rial. In Fig. 2, A represents the container, B the copper cathode with perforations B', D the platinum gauze anodes, and F a diaphragm. The material used as the diaphragm is not mentioned.

Into the cathode space of the cell is placed a solution made up as follows: 500 c.c. contain 32 gr. potassium glyoxalate, 20 gr. potassium sulphate, and 0.5 gr. potassium hydroxide. For this quantity of solution the cathode surface should be about 200 sq. cm. About 60 cc. of 5 per cent sulphuric acid is introduced into the anode chamber. The cathode solution is agitated and electrolytic reduction is carried on with a current density of about 1 to 4 amp. per sq. dcm. The temperature is kept at about 25 deg. C. and should not exceed 40 deg. C. In about 2½ hr. reduction is complete. The potassium sulphate is added to increase conductivity and prevent glyoxylic ions from being carried into the anode compartment. The solution should be neutral or slightly alkaline.

After electrolysis, the solution consisting of potassium sulphate, potassium tartrates, and small amounts of oxyate and glycolate, is treated with calcium sulphate to precipitate the tartrates. The solution is filtered and the tartrates (racemic and meso) are separated by well known methods. (1,181,555, May 2, 1916.)

Separator for Electrolytic Oxygen Cell.—A separator of rubber-covered metal designed to be used in an electrolytic oxygen and hydrogen cell such as described in patents No. 1,172,886 and 1,172,887 (reviewed in our issue of March 15, 1916, page 342), is the subject of a patent of HENRY R. SWARTLEY, Jr., of Manhasset, N. Y. (assigned to Davis-Bournonville Company of Jersey City, N. J.). In the cell described in the above-mentioned patents the anodes are surrounded by trough-shaped separators, from which are suspended asbestos sacks which serve as the diaphragm. The separators should be capable of withstanding caustic solution and oxygen, and should be non-conducting. The present patent states some of the objections to various materials. Glass, while not entirely unsuitable, is subject to attack by the caustic electrolyte, and is fragile. High quality, vitreous porcelain presents manufacturing difficulties, and is also fragile. Hard rubber does not have sufficient rigidity. The separator with a core of metal and a covering of hard rubber is stated to produce a practical and efficient separator. The core may be drawn in a press to the desired shape, the rubber is applied in a plastic condition and then vulcanized. (1,176,105, March 21, 1916.)

FIG. 3—INSIDE VIEW OF FURNACE

Nitrogen from Air

Electric Nitrogen Fixation Furnace.—A novel method of forming the arc in an atmospheric nitrogen fixation furnace is described in a patent of JAMES S. ISLAND of Toronto, Ont., Canada. Two sectional views of the furnace are shown in Figs. 3 and 4. Fig. 3 is a longitudinal vertical section and Fig. 4 an end vertical section. The outer casing 1 has a silica lining and is shaped as shown; 7 represents tubular ring-shaped members, triangular in shape, as shown, and having perforations 11 in them to allow of a distribution of the air which comes in through pipes 9. The rotating

FIG. 4—END VIEW OF FURNACE

element 13 has four radial arms holding diamond-shaped sections 18. Binding posts 23 are connected to two or more terminals of a source of polyphase current and a brush at 22 connects with the rotating element and binding post 20. The arc forms when the current is on and the arc is an annular one, due to its being drawn out by the rotating element. (1,179,927, April 18, 1916.)

Miscellaneous

Extraction of Radium From Carnotite.—A process of recovering radium from carnotite ores or concentrates by treatment with sulphuric acid is the basis of a patent granted to HERMAN SCHLUNDT of Columbia, Mo. The inventor has found that a selective extraction of radium can be made by concentrated sulphuric acid, and that the radium sulphate and accompanying barium sulphate, which are soluble in the hot concentrated acid, can be separated practically completely by mere dilution with water. The ore is ground to 20-mesh and boiled with sulphuric acid at about 60 deg. Baume, until a temperature of 230 deg. C. is reached. The acid liquor is then separated from the ore while still hot; the residue is washed with concentrated acid, and from the clear acid liquor thus obtained the radium is recovered by diluting with water. In practice the quantity of water is from five to ten times the volume of acid. After removing the concentrated acid from the residue the latter is washed with water, yielding a blue liquor containing vanadium and uranium compounds. The latter also are found in the dilute acid liquor from which radium sulphate has been precipitated, and by concentrating these liquors, uranium and vanadium compounds tend to crystallize out, while the concentrated acid can be used for treating further ore. (1,181,411, May 2.)

Production of Phosphorus in the Blast Furnace.—A process of producing phosphorus and its compounds, together with phosphoric alloys of the metals, by smelting natural phosphates with metallic ores and fluxes in a blast furnace, is outlined by JOHN J. GRAY, JR., of Rockdale, Tenn., in a patent recently granted him. Tri-

calcium phosphate, silica, coke or charcoal, lime or other basic material, and ores of iron, copper, nickel, etc., are smelted in proper proportions in a blast furnace. Part of the phosphorus passes out of the furnace with the other gases and is recovered as red phosphorus, orthophosphoric acid or in any other desired form. The balance of the phosphorus is combined with the metal derived from the ore being smelted, and is recovered as an alloy of such metal. The process results in a high recovery of phosphorus, due to the maintenance of a molten bath of metal and slag in the furnace, which facilitates the escape of P_2O_5 vapors. The inventor claims that his process obviates the difficulties formerly encountered in attempting to recover phosphorus by blast-furnace treatment. (1,168,495, Jan. 18, 1916.)

Metallurgical Furnaces

Roasting Furnace.—A method of constructing superposed desulphurizing furnaces, patented by HARRY H. SROUT of New York City and assigned to the General Chemical Co., has for its object the regulation of heat distribution and control of temperature on each of the several hearths of the furnace. This is accomplished by a system of flues and conduits, whereby air is caused to extract heat from zones of high temperature and transfer it to zones of low temperature. (1,181,183, May 2, 1916.)

Agglomeration of Sulphides for Pyritic Smelting.—JAMES H. PAYNE of Baltimore, Md., has patented a process of agglomerating sulphide ores or concentrates, with the retention of substantially all the sulphur contained in the original material. For this purpose the ore is heated to incipient fusion in a rotating kiln in a reducing or neutral atmosphere. On discharging from the kiln the material flows into molds and is cooled by water sprays without opportunity for oxidation. The product is specially adapted to blast-furnace smelting where sulphur is utilized as fuel. (1,181,244, May 2, 1916.)

Recovery of Sulphur in Roasting Sulphide Ores.—A furnace particularly adapted to the roasting of sulphide ores and the recovery of the sulphur is patented by HOWARD F. WIERUM of Upper Montclair, N. J. The

FIG. 5.—ROASTING FURNACE

furnace, illustrated in Fig. 5, is of the superimposed-hearth type, and the particular improvements consist in means for introducing steam into the hearths through tangential openings and applying fuel flames to the ore by burners placed on the inner revolving shaft of the furnace, at a point slightly in advance of the rabble arms or immediately following them.

In the illustration, 10 represents the inner hollow

shaft, and 12 indicates openings for rabblers. A burner is shown at 14, being placed slightly in advance of the rabble arm on that hearth. On the outside of the furnace is a bustle pipe 19 through which steam is delivered to tangential inlets 20. It is claimed that this arrangement of burners and steam pipes offers advantages over that arrangement where burners are on the exterior wall of the furnace and steam inlets are directed diametrically across the hearths. (1,162,894, Dec. 7, 1915.)

Treatment of Ore and Recovery of Sulphur.—A furnace in which several operations are conducted consecutively is patented by UTLEY WEDGE of Ardmore, Pa. It consists of superimposed hearths constructed in muffle form, the furnace being divided into three zones of three hearths each. In the upper zone it is designed to eliminate the sulphur from the ore, and to maintain such an atmosphere, by the introduction of steam, that the metal will be converted to the oxide and the sulphur eliminated without oxidation. In the second zone the oxidized metal is subjected to the action of reducing gases, whereby the oxide ore becomes "metallized." The lowest zone of three hearths is intended as a gas producer where carbonaceous matter is burned or distilled, the gases being conducted to the upper and intermediate zones of the furnace as needed.

In the upper zone the oxygen for oxidizing the metal is provided by the decomposition of steam. Atmospheres of 4 or even 6 per cent of oxygen will oxidize metal with inconsiderable oxidation of sulphur, and carbon dioxide will do the same at the necessary temperature. The practical range of temperature for the vaporization of sulphur and the oxidation of metal in the case of iron sulphide is from 1400 deg. to 1600 deg. Fahr.

Conducting the operations as a continuous process effects economy in fuel. The ideal condition would be to generate a strongly reducing gas in the lower zone for delivery at a high temperature to the intermediate zone where the oxidized metal is to be "metallized." After the gas had performed its function in the intermediate zone and having lost to some extent its reducing character, it could be conducted to the upper zone. (1,169,444, Jan. 25, 1915.)

Combined Sintering and Smelting Apparatus.—In several patents granted to ARTHUR S. DWIGHT of New York City apparatus is shown for the combined and continuous treatment of ore by first sintering into a rigid cake and then smelting in a reverberatory furnace. The sintering apparatus is of the type commonly known as the Dwight-Lloyd, consisting of a series of grate-bottomed pallets receiving a charge of ore to be sintered, and successively carrying the charge under an igniting mechanism and over a chamber from which air is being exhausted, with the result that the sulphurous material burns and causes the entire mass to agglomerate into a porous, rigid cake. In the present invention this cake is continuously discharged into a smelting furnace, whereby the heat of the sinter is economized in the smelting operation. The smelting furnace is of the reverberatory type, with fuel-oil or other burners so disposed that their flame will impinge on the entering sinter and fluxes and cause them to separate into matte or metal and slag in the usual manner. (1,169,069-139-384, Jan. 18 and 25, 1916.)

Industrial Preparedness.—The June issue of the *Journal* of the American Society of Mechanical Engineers contains a full account of the exceedingly interesting discussion on "organizing for industrial preparedness" at the New Orleans meeting of that society, April 11 to 14, 1916.

Novel Construction of Storage Buildings

The Griffin Construction Company, Atlanta, Ga., is erecting two cotton-seed storage buildings for the Buckeye Cotton Oil Company's Atlanta mill. The type of construction used is novel and also new for this purpose.

By using a type of tile in which there is a U-shaped groove for holding reinforcing rods the boiler plate originally specified was done away with. In this way it has been possible to reduce the construction cost to as low a figure as \$3.50 per ton of material stored. The buildings are absolutely fireproof, being built of concrete and fireproof tile reinforced with steel. The roof of the buildings will be of steel.

The two buildings are each 75 ft. in diameter and 60 ft. high, having a total capacity of 7000 tons. The floor is of concrete and the foundation extends about 3 ft. below the surface, resting on heavy clay. Fig. 1 is an outside view of the two storage buildings, while Fig. 2 shows clearly the special construction of the tile. Corrugated steel bars placed in the "U"-groove are held in place with concrete. Wet, heavy cinders are placed in the tile under the rods to keep the concrete around the rods. In the first 25 ft. of tile two $\frac{1}{2}$ -in. bars were placed in the grooves, in the next 25 ft. of tile $\frac{5}{8}$ -in. bars are used and in the top 10 ft. of the structure $\frac{1}{2}$ -in. bars. The bottom 10 ft. have two thicknesses of tile while above that point one thickness is used.

The cotton seed is put into the buildings from the top at the center, thus making a cone-shaped pile tending to push down on the sides of the walls instead of sideways. The danger of the walls bulging out is thereby decreased. An "A"-frame steel tunnel runs through the center on the bottom of each building in which a conveyor will be placed which will be used to remove the seed.

Not only is the cost of the structures reduced to the low figure of about \$3.50 per ton of material stored, but by this type of building the insurance rate is cut down to practically nothing.

FIG. 1 TILE FOR STORAGE BUILDING CONSTRUCTION

FIG. 2—STORAGE BUILDINGS

Eight storage buildings of almost similar construction are being built for Swift & Company's mill at Augusta, Ga. W. M. Griffin is the designer.

A Modern Hydrated Lime Plant

The Vermont Marble Company of Proctor, Vt., have just put into operation one of the finest rotary kiln and hydrated lime manufacturing plants in existence. This plant is located at West Rutland, Vt., and was built for the purpose of utilizing waste products from the various operations of the company, their purpose being to turn this waste into valuable chemical, hydrated and agricultural lime products.

The waste material being brought in from the quarries and factories is discharged directly to a No. 6 crusher, unless the lumps are so large that an earlier preparation is required, in which case the material is elevated and put into the large 60-in. x 48-in. Superior jaw crusher. This crusher reduces the stone to 6 in. and under, and the discharge from the crusher is arranged to flow directly into the No. 6 gyratory crusher. Leaving the No. 6 crusher, the limestone is lifted and discharged directly into a rotary screen which eliminates the fines, allowing the coarser material to pass to a 36-in. x 18-in. roll crusher, which reduces to the same fineness as the screen product, both streams flowing directly to a common elevator discharging onto a belt conveyor. At this point the very fines are screened out and conveyed over to the Pulverized Agricultural Limestone Department. The coarser material is discharged to a large circular storage tank, for night operation or for making the operation continuous, and also to the large storage bin above the rotary kiln.

The kiln department has been made sufficiently large so that a second complete unit can be installed, each

HYDRATED LIME PLANT OF VERMONT MARBLE COMPANY

unit consisting of one 8-ft. x 125-ft. rotary kiln with the storage bins and one 5-ft. x 50-ft. rotary cooler. The storage bin above the kiln is arranged with a cradle type of feeder operated from the kiln-driving mechanism, so that the flow of the material is under control at all times.

The kiln is fired by producer gas which is generated in a separate building and led over to the kiln by means of a gas flue. The discharge from the rotary kiln flows by gravity directly to the 5-ft. x 50-ft. rotary cooler. The burned lime discharging from the cooler flows directly to an elevator discharging into the two large oxide bins, through screens which eliminate any coarse or foreign unburnt material.

One of these oxide bins is arranged to feed directly into an elevator discharging to a "Kritzer" six cylinder hydrating machine. The other oxide bin is so arranged that its contents can also be conveyed to the "Kritzer" hydrator, but this bin was installed primarily for the purpose of loading the lime in oxide form directly into cars for shipment.

The hydrating equipment consists of the following:

- 1—No. 4 six-cylinder Kritzer hydrator.
- 2—Air-separating and dust-collecting outfits.
- 2—Beater mills.

Following this equipment there is installed a large compartment bin arranged for packing the various qualities of lime products in a "Bates" four-tube lime packing machine located below, a dust collector system is also installed in connection with this packer.

The stock house is arranged for the storage of the hydrated lime packed in bags. This building has a capacity of from 1500 to 2000 tons.

In the gas producer house the fuel for burning is brought in and discharged directly into a hopper below the track and is then carried by means of a belt conveyor to a crusher discharging directly to an elevator discharging to a belt conveyor leading to the bin above the gas producer or discharging directly to the covered coal storage. This storage has a capacity of from 250 to 300 tons. The gas producer is of the "Chapman" mechanical type, and this producer installation is modern in every particular.

In general, the buildings are of steel frame construction covered with corrugated iron siding and roofing. The various machines throughout the plant are amply proportioned for the various operations and each machine is driven by individual motors.

The power for operating the plant is received from the hydro-electric stations owned by the Vermont Marble Company.

The whole plant is laid out for future extensions.

There is also a department for pulverizing lime for agricultural purposes. This equipment consists of one 33-in. Fuller Lehigh pulverizer with its accessories. An additional stock house and shipping facilities are arranged in connection with this department.

This plant has a capacity of 75 tons of hydrated lime daily and 50 tons of agricultural lime, and in addition to the above, arrangements have been made so that crushed stone for fluxing or other purposes can be shipped.

The large crusher has a capacity of some 240 tons per hour which is sufficient for all later extensions, but this crusher was installed originally for the purpose of reducing large lumps which otherwise could not be handled satisfactorily.

This plant is the most modern rotary-kiln hydrated lime plant in existence. It was designed and constructed by the Fuller Engineering Company of Allentown, Pa.

Large Single Cylinder Engines for Rolling Mills

A single-cylinder engine which has many points of interest and which is finding use in rolling mills, due to its capacity for extreme overloads is the so-called "uniflow" engine. This engine owes its efficiency to the reduction of the loss by initial condensation. The exhaust is at the center of the cylinder, and the engine is, therefore, suitable to wide temperature ranges. Expansion from boiler pressure down to condenser pressure may be carried out in one cylinder with steam economy equivalent to a tandem compound engine. Tests have shown that 200 per cent load can be carried with only 10 per cent increase in steam consumption.

Uniflow engines have been installed for rolling mills in Germany, one of the largest engines on record having a maximum continuous capacity of 6300 hp. and a short duration peak load capacity of 8000 hp. The average load is 4000 hp. This engine is a 67 in. by 55½ in. at 120 r.p.m., installed at the Röchlingschen Steel & Iron Works at Völklingen, built by Erhardt & Semmer, operating with steam at about 130 lb. pressure and 525 deg. Fahr., total temperature (169 deg. superheat) and drives a 30-in. three high mill. A second engine of the same make has a capacity of 1600 to 2400 hp. and is 43 in. by 51 in. at 120 r.p.m., being installed at the Rombacher Iron & Steel Works.

In this country the first uniflow engines for rolling mill work are those now under construction by the Nordberg Manufacturing Company, Milwaukee, Wisconsin, for the Youngstown Sheet & Tube Company, Youngstown, Ohio, the larger to drive a 12-in. rod mill, the smaller a 9-in. rod mill. The general design of the cylinders is shown by the longitudinal section of Fig. 1. The cylinder is a plain cylindrical casting, all valve chambers and steam passages being contained in the heads, bolted to the ends of the cylinder. This prevents distortion and strains due to expansion and contraction with the use of high pressures and superheats. The steam valves are of the poppet type, the valve cages being separate castings which are ground into the heads with a steam tight joint. The valves are of the double beat, balanced poppet type and no packing is required for the valve stems, which are accurately ground and polished and work in ground and lapped bushings. The valves are operated from lay shaft by a releasing valve gear with spring dashpots, the cut-off being under control of the governor through the wide range of loads. The steam enters the cylinder at the bottom, sweeping up over the heads and jacketing them before entering the valve at the top. The exhaust is through the ports

FIG. 1 LONGITUDINAL SECTION OF CYLINDER OF NORDBERG POPPET UNIFLOW ENGINE

in the center of the cylinder uncovered by the piston near the end of its stroke. Relief valves of the poppet type with cataract dampening device are located near the bottom of the heads. In case of loss of vacuum and over-compression these valves automatically open and connect the clearance space of the cylinder with the steam space in the head and the communicating steam piping. The steam conditions will be approximately 170 lb. pressure, 75 deg. superheat, and 20 in. vacuum, steam being condensed by barometric jet condensers.

The larger engine is 44 in. by 50 in., 110 r.p.m. and will have a capacity from 700 hp. to between 3000 and 4000 hp. The weight, including 110,000 lb., 10 ft. flywheel, will be 480,000 lb.

The second engine is a 37 in. by 48 in. at 110 r.p.m. and its weight, including a 90,000 lb. flywheel, will be 360,000 lb.

Alunite in British Columbia

Deposits of alunite have recently been discovered on Vancouver Island in British Columbia, according to Commerce Reports. The analysis of the alunite-bearing rock shows a lower potash content than the high-grade deposits in Utah. Following are analyses of three samples taken from different places in the deposit.

Vancouver Alunite.	No. 1	No. 2	No. 3
Silica.....	52.00	55.65	44.40
Alumina.....	19.85	16.30	21.80
Sulphuric acid.....	16.00	15.10	21.40
Oxide of iron.....	2.45	2.15	7.70
Potash.....	5.60	4.30	4.50
Water, etc.....	4.40	6.50	7.20
Total.....	100.00	100.00	100.00

The results of the above analyses might be compared with three typical analyses of the alunite from Marysville, Utah:

Utah alunite	18	19	Dana
Alumina (Al ₂ O ₃).....	37.18	34.40	37.00
Ferric oxide (Fe ₂ O ₃).....	Trace	Trace	Trace
Sulphuric trioxide (SO ₃).....	38.34	36.54	38.60
Phosphorus pentoxide (P ₂ O ₅).....	.58	.50	
Potassium oxide (K ₂ O).....	10.46	9.71	11.40
Sodium oxide (Na ₂ O).....	.33	13.08	13.00
Water (H ₂ O plus).....	.05	.11	
Water (H ₂ O minus).....	.22	5.28	
Silica (SiO ₂).....	100.10	100.18	100.00

There is a possibility that more extended investigations of these deposits may bring to light a higher grade of rock. This possibility is shown by the fact that a small sunken island some little distance from the mainland contains rock of a much higher potash content than any of the samples above enumerated from Vancouver, all of which were collected at a short distance from the coast and on the hillsides.

Raw alunite has already been largely used directly as a fertilizer with manifest advantage. The roasted mineral, however, gave double the yield in increasing the crops when experimental comparisons were carried out on similar tracts of land.

Moving Pictures at the Second Exhibition of Chemical Industries

The many favorable comments received on the showing of the motion picture films at the 1915 Exposition of Chemical Industries, led the management of the coming Second National Exposition of Chemical Industries to be held at the Grand Central Palace, New York City, week of Sept. 25, to arrange a motion picture program broader in scope than that prepared for the former exposition.

Many films have been secured during the past six months from large industrial corporations throughout

the country through the Bureau of Commercial Economics at Washington. These motion picture films will be shown daily during the Exposition and will be of special interest to every visitor.

Among the films already arranged, are the following showing:

The Match Industry.
The Rubber Industry.
Manufacture of Explosives.
Varnish Manufacture.
Silver Mining.
Mining and Manufacturing of Iron.
Making of Blotting Paper.
Accident and Fire Prevention.
Manufacture and Use of Fertilizers.
Manufacture of Steel.

The motion picture program will include films of such industries that are dependent upon chemistry.

Arrangements have also been made to exhibit the motion picture film taken of the members of the American Chemical Society in Danville during their Spring meeting in April.

The managers report they have at this time twice the number of exhibitors they had last year at the Exposition, and much new apparatus and processes will be exhibited for the first time at the coming Exposition. In no other exposition of any kind can the technical or business man find so much of vital interest and real immediate benefit to repay him for a visit.

Personal

Mr. G. M. Bissel has become associated with the steel-car sales department of Kilbourne Jacobs Mfg. Co., Columbus, Ohio.

Mr. J. A. Burgess has resigned as superintendent of the Wonder Nevada Mining Co., to become general superintendent of the United Eastern Mining Co., Oatman, Ariz.

Dr. Frank K. Cameron, formerly in charge of the fertilizer investigations of the U. S. Bureau of Soils and chemical engineer with the Utah Potash Co., a company operating on the property of the Florence Mining & Milling Co., Marysvale, Utah, is now in Washington, D. C., where he has taken up consulting work with special reference to fertilizer problems.

Prof. Joseph Daniels, assistant professor of Mining and Metallurgy, University of Washington, at Seattle, Wash., departed from the university as soon as the college year closed, recently for Thane, Alaska, to engage in practical study of mining through work in the Alaska-Gastineau mill, where he will have the opportunity to observe and study the processes of breaking, rolling and concentrating as applied to low-grade gold ore. Mr. Daniels will be away from the University until the middle of September.

Mr. Ralph L. Fuller, vice-president of Harshaw, Fuller & Goodwin, manufacturers of chemicals, was elected president of the Cleveland Chamber of Commerce at its recent annual meeting.

Mr. E. R. Grasselli, second-vice-president and treasurer of the Grasselli Chemical Co., is vice-president of the chamber.

Mr. H. A. Guess has been appointed managing director of the mining department of the American Smelting & Refining Co.

Mr. C. F. Harrington, mechanical engineer formerly with the New York Central Railroad, is now sales engineer with the Powdered Coal Department of the Bonnot Co., Canton, Ohio.

Mr. Maxim L. Kagan, general manager of Franz Krull, Ltd., Reval, Russia, who is here on Government business, has just placed an order with H. L. Barnitz, sales agent of the International Oxygen Co. for a large oxyhydrogen plant of the unit-type generators; the gases produced by this plant to be used for welding and piped throughout their works. Mr. Kagan recently placed orders on refrigerating machinery for the Russian Government aggregating over half a million dollars.

Mr. G. S. Kelley, formerly with the Digger Machinery Co., Inc., has recently been appointed sales representative of the John F. Allen Co. of New York, in connection with the new department they have established for the manufacture of coal-handling and hoisting machinery.

Mr. Isaac H. Levin announces that he has resigned as chief engineer and chemist of the International Oxygen Co. in order to devote his time to chemical research and as a specialist in the electrolytic field. His temporary address is 186 Hillside Ave., Newark, N. J.

Mr. Arthur D. Little, of Boston, Mass., is at present, together with Mr. George Bury, vice-president of the Canadian Pacific Railway, on a trip of inspection through Canada to Vancouver. As was formerly noticed in this journal, Mr. Little and his firm have been retained by Lord Shaughnessy, president of the Canadian Pacific Railway, to assist in carrying out extended plans for a scientific research of Canada's natural resources. Mr. Little's present trip is for the purpose of making a preliminary investigation of the situation and laying out the plans for the future work of his staff.

Mr. H. W. Sparks, sales manager of the Kalbfleisch Corporation, Chattanooga, Tenn., was in New York a short time ago at the office of the Franklin H. Kalbfleisch Co.

Industrial Notes

The Norton Co., Worcester, Mass., has issued a new catalogue describing its grinding wheels and machinery. It is beautifully illustrated and contains much information on alundum and crystolon besides the various products made from them.

Microscopes and Accessories.—The Bausch & Lomb Optical Co., Rochester, N. Y., has issued a new catalogue describing Bausch & Lomb microscopes and accessories. This is the twenty-fourth edition, the first having appeared in 1874. The present catalogue offers the most complete line yet presented. Of especial interest is the new complete series of apochromatic objectives, the first to be offered by an American manufacturer.

Portland Filter.—The Colorado Iron Works Company, Denver, Col., has issued pamphlet No. 28-B, describing the Portland Filter. The description is very complete and includes all the details of construction, together with a list of users of this filter.

Electroplaters Convention.—The 1916 meeting of the American Electroplaters Society will be held in Cleveland, Ohio, from July 6 to 8. It is the intention to spend less time on business meetings and more time on papers and discussions than at previous meetings.

A. H. Ney, Inc., announces that they will continue the business of consulting chemists and chemical engineers, heretofore conducted under the name of A. H. Ney, Ph.D. The new company has been organized to provide increased facilities for its clients in consulting and chemical engineering work, in connection with

the installation of plants for the organic chemical industry. The chief lines embraced will be dyes and intermediates, high explosives, medicinal chemicals and photographic developers.

The Vulcan Soot Cleaner Co., of Du Bois, Pa., state that their New York representatives, the De Ved-Kissick Co., 149 Broadway, New York City, have recently obtained a large order for the type of apparatus manufactured by that company. Vulcan soot cleaners are to be installed on fifty boilers of the B & W type, totaling 30,000 hp. rated capacity, at the Marion plant of the Public Service Electric Co. of New Jersey. In this plant the boilers are set singly with dusting and blow doors on each side, through which a hand steam lance was inserted for hand blowing, these being favorable conditions for soot cleaning by hand as compared to plants where the boilers are set in batteries and have to be cleaned entirely from one side. It was considered more economical, however, to equip the plant with Vulcan soot cleaners. With mechanical soot cleaners the boiler tubes can be kept clean and more efficient in absorbing heat with much less cost for labor.

Common Sense of Export Trade.—In an address before the Executive Club of Chicago, on May 26, Stanley H. Rose, at that time commercial agent of the Bureau of Foreign and Domestic Commerce, but now with the Barber Asphalt Paving Co., discussed some of the important points connected with building up of our export trade. One of the chief difficulties which he mentioned was the lack of young men trained in foreign languages and in export trade and having first-hand experience in foreign countries. Another difficulty is the shortage of American ships. Our export trade is increasing gradually, but we could sell ten times more or perhaps a hundred times more, if we realized the importance of going after the business as soon as possible.

Paul O. Abbé, 30 Broad Street, New York City, has issued Catalogue "B," which includes descriptions of disintegrators, caged mills, crushers, the improved rotary cutter and other apparatus. Considerable space is devoted to the rotary cutter, which is used in a great variety of industries, in the reduction of various materials.

Cellulose in Wood.—The Forest Products Laboratory, Madison, Wis., has perfected a method of determining the chemical constituents of wood. From tests made it has been found that the production of cellulose in modern pulp-making is from 5 to 20 per cent less than the amount in the wood.

The Yaryan Rosin & Turpentine Co. will build a \$250,000 wood pulp plant at Brunswick, Ga. This plant will be operated in connection with the company's distilling plant and will produce Kraft pulp. It is also claimed that a cheap gasoline can be produced from the company's products.

Increased Production of Manganese Ore.—The production of manganese ore in 1915 was 9651 long tons, the largest since 1901 and more than three times the 1914 production, according to the Geological Survey. The imports were 313,985 tons showing the comparative insignificance of our domestic production. Eighty-five per cent of the imports came from Brazil, and about 36,450 tons came from India. None was received from Russia. The production in the United States of manganiferous iron and silver ores was 798,404 tons, which was almost twice the 1914 output. This was mostly used in making high-manganese pig iron, but some was used as a flux by lead smelters and some to make low-grade ferromanganese.

Factory Notes is the title of a monthly pamphlet published by the United States Cartridge Co. of Lowell, Mass. The first number appeared in February, 1916. The Welfare Association of the company has evidently a great deal to do with the issue of this paper. Among its councilors is Mr. H. B. Coho, the widely known former secretary of the New York Section of the American Electrochemical Society. According to the June issue of *Factory Notes* the latest undertaking of Mr. Coho is the formation of a United States Cartridge semi-military company or battalion.

The Improved Equipment Company, New York City, has entered into an agreement with Waldo Brothers, Inc., Boston, Mass., whereby the latter will act as agents in the New England States for coal gas plants, and accessory apparatus designed by the Improved Equipment Company.

Cooling and Cleaning Air for Generators.—The Carrier Air Conditioning Company, Buffalo, N. Y., has issued Bulletin No. 253 describing Carrier cooling and cleaning systems for generator and transformer ventilation. The booklet gives a description of the Carrier air washer and explains the increased power obtained by cooling and washing the air which is used in ventilating a generator.

Association of Chemical Manufacturers formed in Great Britain.—At a meeting of chemical manufacturers held in London on May 23, it was decided to form an Association of Chemical Manufacturers, in order to aid in the building up of the chemical industries in that country, and to help them meet foreign competition after the war. A committee was appointed to prepare plans for the new association.

Poidometers.—The Schaffer Engineering & Equipment Co., Tiffin, Ohio, has issued Bulletin No. 5, describing the Schaffer poidometer with liquid measure attachment for automatic weighing of miscellaneous materials. The liquid measure attachment is a device which delivers a predetermined number of pints per minute in proportion to a predetermined number of pounds of solids on the poidometer, giving a mixture of any desired consistency.

Peat Powder for Railroad Use.—A report has been made concerning the use of peat powder by the Swedish State Railways, according to Commerce Reports. This report discloses the fact that the administration of these railroads has requested the King to propose a bill in the present Riksdag for an appropriation for the erection of a peat-powder factory for their use. The report is as follows:

The investigation concerning the possibility of using peat powder for the locomotives of the State railways has now been finished and the railway directors have placed the results before the King. They have also requested the King to propose a bill in the present Riksdag for an appropriation of 1,300,000 crowns (\$348,400) for the erection of a peat-powder factory at the Hästagen bogs and for the use of enough locomotives for peat powder so that all the trains on the Falköping-Nässjö line may use this fuel.

After a careful examination the railway directors state that they have found peat powder to be very efficient and practical for locomotives, with a fuel value, compared with that of coal, of about 2 to 3. The ratio of peat powder will probably be greater when it has been used and experimented with further. Therefore it is considered a good thing to use peat powder, especially as the country's own resources will be utilized.

In order not to have to depend on private industry and the fluctuations of the market, the directors thought it would be advisable for the railways to have a peat-powder factory of their own, and estimates of the cost of erecting a factory have been given. The Hästagen bogs have been chosen as a suitable place, as it is estimated that 20,000 tons of peat powder can be produced there annually for twenty years. This amount is required by the Falköping-Nässjö line for that period.

Using the ratio given and calculating from the lowest estimate for its production, the cost of peat powder, per ton, would be 15 crowns (\$4.02) and the corresponding price of coal would be 22.50 crowns (\$6.03) per ton. When calculating the price at 15 crowns per ton the items included are: Cost of running the factory, interest on the cost of changing locomotives for the use of peat powder, patent cost, and royalty. The company that erects the factory will charge 25,000 crowns for the use of the patent and 50 ore (\$0.134) per ton of peat powder as royalty.

The 1,300,000 crowns asked for would include the cost of buying the bog and sufficient solid ground, the erection of the factory, patent cost, cost of tracks to the bog, and cost of changing the locomotives.

Book Reviews

Materials of Construction. By G. B. Upton. Octavo (14 x 23 cm.), 327 pages, 181 illustrations; price, \$2.50 net (10/6 net). New York: John Wiley & Sons, Inc.; London: Chapman & Hall, Ltd.

This book covers the structure and properties of the more common materials, being an outgrowth of a laboratory course given by Professor Upton to junior students at Cornell University.

Part I deals with the experimental determination of properties, such as the common mechanical tests, aging, corrosion, rusting, etc. This part is elementary, the discussion being largely based on the internal condition of the material during the test.

Part II discusses the internal properties of materials by metallographic study, and their control by mechanical and heat treatment. It would appear as if this should have preceded Part I, because the phenomena thus determined are made the basis of the analytical treatment of the substance of Part I.

Aside from this, the discussions of Part II, which is really a short study in theoretical and applied metallography, are entirely beyond the field of the usual engineering student; its explanations being in hypotheses of physical chemistry which are doubtful or even dubious, its theories are somewhat overloaded in bearing the weight of the phenomena which they are called on to explain.

Mechanical Technology. By G. F. Charnock. Octavo (13 x 21 cm.), 635 pages, 503 illustrations; price, \$3, net. New York: D. Van Nostrand Company.

The sub-title indicates the field covered as the materials and preparatory processes of the mechanical industries. One-fourth of the contents cover the production and properties of the metals and alloys, another fourth their molding and casting, another various mechanical operations involving their change of shape by forging, stamping, rolling, drawing, spinning, pressing, etc., and there are some minor chapters on timber, stone, abrasives, lubricants, rubber, leather, rope, etc.

The part treating of production and properties is necessarily a brief summary of a very large subject, of very little use to a metallurgist and of little real value to a civil, electrical or mechanical engineer; the foundry section is better; the section on mechanical working is a good summary for metallurgists and chemists, in fact, for them the most valuable part of the book, because of its condensed character.

The metallurgical part is poorly written and its chemistry is weak; the book would be much more useful and reliable if its first 160 pages on production and properties were condensed into, say, 50 pages on properties alone, leaving the student to find production of metals and alloys in books or treatises written by competent metallurgists. The mechanical practice described is mostly English, and does not correspond in many cases to best American practice.

The New Phase in the Dyestuff Tariff Fight before Congress

A new dyestuff tariff bill has been placed before Congress, together with the general revenue bill of the Administration. The dyestuff tariff fight has thereby entered into a decidedly new phase.

That almost certainly a new dyestuff tariff will be enacted by the present Congress means two very important things. First, that everybody in Congress agrees that it is a vital necessity for the American nation to be self-contained with respect to the dyestuff and allied industries. Second, that everybody in Congress now agrees (and this has never happened before) that the creation and the sound development of a general dyestuff industry is impossible without a protective tariff sufficiently high to give real protection and not merely yield revenue.

This is, in fact, a big achievement and full credit must be given to the Administration and to Congress for having agreed on the principle. It is clear proof of an earnest desire of the Administration and of Congress to deal with the chemical industries with that degree of fairness of consideration to which the chemical industries are entitled in view of their fundamental importance for the nation, but which has not always been accorded them in the past.

As an agreement has now been reached on the principle, it should not be difficult to discuss the remaining differences intelligently without excitement. The present situation may be summed up as follows: All agree that the present Underwood tariff is insufficient. But the representatives of the chemical industries insist that the rates of the Hill tariff bill represent the minimum necessary for real protection, while the Kitchen tariff bill now before Congress grants less.

One decidedly novel feature of the Kitchen bill (which is given in detail on page 65 of this issue) is that it sets a time limit on the surtax. As it is an infant industry that is to be protected no one can object to the fairness of the principle of the time limit. The question of how long a new industry is an infant and needs protection, remains open. But as this is a matter which can be adjusted or corrected in the future, we may dismiss this fundamentally most interesting feature of the Kitchen bill from our present discussion.

There remain two important differences between the Kitchen bill and the Hill bill and these deserve immediate attention. The first relates to the amount of protection. As the detailed differences between the rates of the Underwood, Kitchen and Hill bills are given on page 65, it will be best here to bring out these differences by another rather instructive method for which

we are indebted to Dr. B. C. Hesse, one of the foremost authorities on the subject. Dr. Hesse bases his discussion on the amount of importations of dyestuffs and intermediates into this country in 1913. The duty on these according to the Underwood tariff is \$2,298,632, while it would be \$4,999,084 for the Kitchin bill, and \$6,908,648 for the Hill bill. In other words, where Underwood grants \$1.00 protection, Kitchin proposes a protection of \$2.18, Hill of \$3.00. (Of course, with a different proportion of the importations of aniline dyes, of alizarine and anthrazene dyes and indigo, and of intermediates, the proportion indicating the relative protection afforded by the Underwood, Kitchin and Hill tariffs respectively would be somewhat different from 1 to 2.18 to 3, but these are the best figures available.)

Now what does this really mean? This country wants to add a new industry to its national household. Is it wise to haggle and try to do for \$2.18 what all experts agree costs \$3.00 if it is to be done right? If an individual house owner wants an addition made to his house and on expert advice finds it will cost him \$3,000 to have it done right, he would certainly hesitate a long time before trying to find somebody who would agree to do something for \$2,180. If he is wise he will decide to have it done for \$3,000 if it is to be done at all. Can the American nation afford to be less judicious if it really wants an American dyestuff industry?

The second important difference is that the Hill bill tries to protect the industry all around, the Kitchin bill does not, as it exempts alizarin and anthracene dyes and indigo from the surtax. We cannot do better than quote Dr. B. C. Hesse's comment on this feature: "If you were building a high board fence around your vegetable garden to keep your neighbor's chickens out would you build three-fourths of the fence so that it went well into the ground, and leave the other one-fourth 3 ft. from the ground on the theory that the chickens would not find this weak spot in your fence? In exempting anthracene, alizarin and indigo dyes and indigo from the surtax, that is precisely the theory on which the Kitchin bill proceeds, and it offers, at the suspended portion of the fence an added bait for the chickens, by threatening to remove the surtax unless 60 per cent of the value of our total consumption is produced in this country within five years. This is about the same as if, in addition to building the fence as just described, you industriously sprinkled a lot of 'chicken feed' so that it leads directly to this hole in your fence. This is the strategy of the Kitchin bill."

A wonderful beginning has been made by American dyestuff manufacturers during the past few years. To accomplish more—to accomplish all that this nation has a right to wish for—they now need the support of the nation as represented by Congress. And Congress has made a wonderful beginning by grasping correctly the principal point of the situation.

Having shown a broad attitude of mind in the matter of principle, Congress can hardly afford to spoil its work by narrowness in fundamentally important details. We sincerely hope that the provisions of the Hill bill will be enacted into law.

Increased By-Product Coking

No criticism can be made of the rate at which the iron industry is now adopting the by-product coking process. In the earlier years the progress was slow. It was not until 1900 that an output of a million tons of by-product coke was attained and ten years later the output was only 7,138,734 tons. Last year the output was 14,072,895 tons, representing a doubling in five years, a fairly good record, but not a very good one, considering the great promises of profit. In the earlier years, however, the iron industry had to finance its by-product oven construction largely out of profits, and frequently these were not large.

Of late financial machinery has been available whereby such new construction could be much more readily undertaken.

With an output during last year of 14,000,080 tons, the capacity available at the close of the year may be estimated at considerably more. Several batteries of ovens have since been completed and much construction work is in progress, the present program indicating that new plants, of from say 50 to 200 ovens, are to be completed at an average of about two per month during the next six or nine months. The by-product coking capacity a twelvemonth hence will probably be close to 25,000,000 tons, representing between 40 and 45 per cent of the prospective coke requirements of the country, which may be estimated at not far from 55,000,000 tons.

Necessarily a great many beehive ovens must be abandoned, for the increase in the production of by-product coke is very greatly in excess of the increase in consumptive requirements. The production of beehive coke, indeed, reached its maximum as long ago as in 1907, and the decreases since then have not been due entirely to ovens being abandoned because the coal over which they had been located was worked out. The condition of forced abandonment of beehive ovens makes it that the coal remaining becomes available and there is less search for new and cheap coal for by-product use than was expected. Connellsville and Pocahontas coals are already being shipped in a large way to by-product ovens. In many instances, indeed, the by-product ovens are built by furnace interests having beehive coking operations, the beehive ovens being simply abandoned and the coal shipped to the new ovens, to be used perhaps in conjunction with smaller proportions of coal from other districts.

By far the major part of the by-product coking now being done or in prospect involves the recovery of little of the by-products apart from the gas, and it is evident that when by far the major part of the coke is being made by the by-product process there will still be a great deal of work to be done by way of installing the adjunct processes for various recoveries of the other valuable products.

Dirty Oils

Oils are delicate bodies, complex in composition, and those of vegetable or animal origin are very likely to decay if they are not properly treated. It is not con-

sidered good form to let a dead pig lie around until it becomes a nuisance and then proceed to secure the lard from it. But many oils which are as complex in their constitution and as subject to decay as lard are handled in such a manner that no plant or animal could live and contain them in the condition that they are brought upon the market. It is safe to say that millions of dollars are annually lost in the United States on oils that were originally good and that could have been kept good, but have gone bad. Oils should be refined as soon as possible after they are pressed because organic oils have a way of increasing like rabbits, once they get started, and while the cottonseed oil industry, with its problems of transportation and the signal chemical talent engaged in it may well be allowed to take care of its affairs without gratuitous criticism, there are other oils that come to market in a condition that calls for a little investigation as to their sources and then a little admonition and wholesome advice to their producers.

The tropics sometimes seem hopeless. Some presses lately sent down and set up at a convenient tropical station were not operated on the ground that they were too heavy for women and children to work them. A little civilization is creeping in and it occasionally shows in the oils; but civilization grows delicate when it reaches the tropics and care must be taken that it does not grow thin from loss of temper.

Peanut oil, coming from France, is much better prepared than any domestic product—or at all events the most of our domestic product—and there is no reason for this at all. When peanuts are pressed in their husks, in an old cottonseed press that has not been cleaned out, it indicates a looseness of method that should be corrected. There's no use in letting things get down at the heel that way. When we consider what careful treatment oils need the time seems ripe for calling for better factory practice in their preparation. A great deal of trouble will be avoided if more attention is paid to this first step in the industry.

Blast Furnace Performance

The blast furnaces of the United States have disclosed quite accurately in the past six months what they can do. There have been only minor variations in the rate of output, and these are attributable largely to weather conditions. There were increases in February and March and a further increase in May, while production fell off a trifle in June. The performance seems to have been quite in line with conditions as to humidity in the atmosphere, and as both the steel interests and the merchant furnaces have been striving for maximum output the actual production seems to be an accurate index to the average commercial capacity. This may be taken at an average of 39,500,000 to 40,000,000 tons for a twelvemonth, with its periodic variations in weather conditions.

It is commonly said in the iron industry that after a period of relative inactivity the furnaces are found to be in good physical condition, all nicely relined, etc.,

whereby they can stand a strong campaign for a time, but that after such a campaign so many must go out for relining that the production is then reduced. There has been no case in actual practice of this theory being substantiated. Production declines only when the weather becomes unfavorable or the demand for iron decreases, and sometimes in the latter case it does not decrease altogether as promptly as it should. There is no reason to believe that the existing furnaces could not make close to 40,000,000 tons of pig iron in the twelve-month from date.

One new blast furnace was completed and blown in May 13 and another on June 5, while nine stacks are now in course of construction, their average date of completion being perhaps about six months hence, while all the new stacks should be completed within a twelvemonth, if market conditions continue such that rapid construction work is desirable. The country's commercial capacity may then be taken at about 41,500,000 tons a year.

Only a qualified statement as to capacity, however, can be made, as commercial conditions vary. At the present time an unusually large amount of spiegeleisen and ferromanganese is being made, the tonnage output being counted simply as "pig iron," whereas the output per stack is much less than if real pig iron were being made. One does not know whether the furnaces will make more or less of the manganese alloys in future, that being a matter of commerce, not of physical capacity.

Again, in the whole history of the blast-furnace industry there have been furnaces falling by the wayside. They are not kept up to date physically, or conditions change as to supplies of raw material. They are not abandoned immediately upon their last blast, as the owners are disposed to wait for something to turn up. Under exceptional market conditions, with high-priced pig iron and relatively low-priced raw materials a furnace supposedly out of the running may become active, while in reverse conditions a furnace supposedly fit may have to be counted out. Thus the commercial capacity of the country really varies by a complicated formula, in which there are factors of demand, market prices of pig iron and raw materials, wage rates and other items. What is called "demand" is a separate factor, for there have been times when the going market price appeared sufficient to bring an idle stack into blast, but it was impossible to sell sufficient tonnage at the price to justify incurring the lump sum expense of blowing in the stack. Thus one can hardly say more than that under present commercial conditions the actual blast furnace capacity is in the neighborhood of 39,500,000 to 40,000,000 tons, and is destined to become 41,000,000 to 42,000,000 tons within a twelvemonth. The existing capacity proves to be larger by several million tons than was estimated before the furnaces were subjected to their present test. As a rule the individual outputs have exceeded previous outputs and sometimes they have surprised the managers themselves.

Readers' Views and Comments

Liquid Jets

To the Editor of Metallurgical & Chemical Engineering

SIR:—In your issue of June 15 I read with interest the comments of Mr. B. DuFaur upon the article of Mr. C. Terry Durell regarding liquid jets, which appeared in your issue of March 1 last.

Mr. DuFaur states that the liquid jet was used in Australia as early as 1908. It is quite well known that it was used in America some years before that time for the purpose of efficiently commingling a liquid and gas under pressure.

During the year 1903 I used the liquid jet as a fume arrester. The entire arrangement consisted of a 2-in. centrifugal pump, a small tank, a nozzle and its housing, and the necessary piping to connect all into a continuous circuit. The nozzle with its housing appeared as a very large filter pump and patterned after the one commonly used in the laboratory.

When the entire arrangement was to be placed in operation, the tank was filled with the liquid and the centrifugal pump started, it being supplied by the liquid in the tank. The liquid was thus forced by the pump through the nozzle and then delivered to the tank with its burden of commingled gas. The liquid was then taken up by the centrifugal pump again, and thus continuously circulated.

About the time mentioned above or shortly thereafter I applied for a U. S. patent covering the arrangement as a fume arrester. The patent was allowed but I never took it out. I learned through the patent office that practically the same thing had been patented some years before for the purpose of purifying illuminating gas.

During the year 1905 I conducted experiments upon a much larger scale at the property of a mining and smelting company of Utah. In these experiments I used a 10-in. centrifugal pump but the cost of pumping was excessive. Under the most favorable conditions the amount of free cold gas drawn into my apparatus approached one volume for every volume of liquid passed through the nozzle.

This method was used by me quite frequently to aerate cyanide solutions, and during the last few years I have made numerous flotation experiments by use of the method with varying degrees of success.

HENRY R. ELLIS.

Buttering Wages

To the Editor of Metallurgical & Chemical Engineering

SIR:—Far be it from me to urge the love of money upon people. The general impression prevails that we have enough of that sort of thing in this country, and I have no desire to contradict it. But when I consider the habits of life that prevail in many places, which are too low to entertain thrift, I begin to doubt the old saw that the love of money is the root of all evil.

There is a great deal of work to be done in this world and most of us need an incentive of some kind to induce us to lend a hand. This applies to all of us: masses, classes, member of manufacturers' associations, boards of trade and the I. W. W. It is also worthy of note that the art of getting work done seems to involve something more than the payment of wages. It appears that wages need to be buttered in some way to make them acceptable, and to neutralize their bad

effects. Let us consider a few examples from fact and fiction in which it is indicated that high wages may fail to pay.

I once had a skilled workman in my employ, in charge of a kettle. The man received \$2 a day. He was a good man, intelligent, industrious and willing. He then received authority over three kettles and two helpers, his pay being increased to \$2.50 a day. In time he achieved supervision over all the kettles; his wages were \$3 a day, and I was relieved of the constant agony of watching the kettles and the fear that some careless laborer might waste several hundred dollars worth of material.

Close at hand was another operation that needed occasional watching. This was a much lighter task, but attention was important. The foreman was sure he could look after it with ease. Subsequent events proved that he could, and for this he received 25 cents more per day, making in all \$3.25. There seemed to be some devilment in that last quarter. The foreman grew pompous and vain, he bullied the men under him until the best ones left, he conceived the idea that he should be made an elder in the church, and he caused so much trouble in the community that he had to be laid off for a while. There was something wrong in that last quarter; the employer lacked wisdom by not buttering it properly.

In a late number of *Punch* there is depicted a washerwoman who tells her mistress that she cannot continue to wash for her because her man has employment and is earning so much that the last week they had been obliged to put some of their earnings in the bank, and if they did not look out they would be compelled to do the same thing again. This is probably taken from fancy, but it is not an impossibility, as we shall see. The psychological problem is simpler in this case; what the woman and the husband lacked was a knowledge and understanding of the art of administering funds.

Now comes a report of Mr. Richard I. Austin, the Federal Reserve Agent of the Philadelphia district, in regard to the business situation with special reference to the attitude of labor. Mr. Austin says:

"There is universal complaint that as wages are increased a large class of wage-earners become less productive, and the failure of industrial plants to make sufficient or reasonable output is preventing the realization of much, if any profit from operations. The attitude of wage-earners is disappointing. Instead of taking advantage of the present wonderful opportunity to make large earnings, they are apparently not netting much more than formerly, when wages were much lower; the cost of living for them, as for others, is much higher, and the whole country is suffering a great economic loss through the failure of our industrial establishments to produce the volume of goods for which there is at present so great a demand."

There we have it. The week's work is cut down to five days and even less, and because labor is scarce the competent members of the force let down in speed and efficiency. Now there is no use in saying that they are a pack of fools, because they are not. The fact is they are started wrong, their leading is bad, and their philosophy is contrary to what the rest of us believe in public welfare. If laborers were to engage in habits of thrift they would be in a position to make better bargains for themselves when times are hard, because

they would not be under the drive of need to take any work at any wages when both are scarce. They still could bargain and show the value of competent workers over the incompetent ones; they could prove their point and get work, because employers are always out for profits, and they want steady hands.

The argument that has won against this is that of collectivism, in which it is held that they who labor are a class by themselves, the competents and incompetents together, and that whatever will injure the owners of the work is of just that measure of advantage to labor. This is not true, because unless labor keeps in form and keyed up to capacity it can neither administer affairs nor work for itself. Capital selects its instruments with care and drops out sloths, incompetents, booze-lifters and dull-wits to shift for themselves. Capital is selective while labor is collective, and while this does not prevent the two from fighting or hinder labor from running capital, it does prevent labor from winning. Without the discipline of efficiency, speed, thrift and independent thinking, those who are weak of will drift over from competence to incompetence, and a gradual degeneration of labor and production takes place. Labor can do nothing with that incubus.

Why, then, have misleading arguments and a false philosophy gained such headway among laborers? It is not because of the stupidity of laborers. It is because the arguments have been presented to them with greater conviction and superior ability than the arguments for industry and thrift which employers claim to preach. The arguments of the employers have been feeble and without enough interest to make them carry. Labor can come into its own, the productiveness of this country can be increased beyond the dreams of to-day, and the feeble of mind, body, and will can be employed at least so that they support themselves, if only labor will avail itself of that worldly wisdom, without which goodness itself is likely to fail. The stupidest thing on earth is to fight windmills. Next in order of stupidity is the cultivation and development of habits of inertia—of laziness. These two things will kill progress anywhere and any time.

I lately read a letter from a man in prison approaching the end of a long sentence at hard labor. "No matter how you feel," he wrote, "You can't get even with the State or with Society, which has turned you down, by shirking work. My companions call me all sorts of a fool for being a willing worker, but I don't mind that because in this very thing lies my only hope. If I let myself get into the condition in which sustained and hard work is impossible to me—and nothing is easier—then I shall be no good when I get out. And I don't want to come back here a little bit. That is the trouble with the bums here; they can't work more than a few days in succession no matter how hard they try. They are sure to come back."

PETER TEN BROECK.

American Electrochemical Society, New York, Sept. 28-30.

American Society for Testing Materials

An account of the first day's meeting, excepting part of the evening program, of the American Society for Testing Materials' meeting held at Atlantic City, June 27 to 30, was given in our issue of July 1.

Following the presidential address on Tuesday evening an exceedingly interesting paper on the "Hardening and Tempering of Eutectoid Carbon Steel and on the Shore Test," by HENRY M. HOWE and ARTHUR G. LEVY, was presented by Professor HOWE. A paper entitled "Experiments on the Plastic Elongation of Wires" was read by A. V. DE FOREST. This paper contained a description of a sensitive apparatus for observing the "creep" or slow stretch of wire under load, and recording the stress deformation diagram on photographic paper. The paper was discussed by Professor HOWE.

The report of Committee D-1 on "Preservative Coatings for Structural Materials" was read by P. H. WALKER, chairman, and a paper on the "Acceptability of Linseed Oil" was read by C. D. HOLLEY. This paper, which was a discussion on the question of "foots" in linseed oil, elicited further discussion from Messrs. G. H. PICKARD and H. A. GARDNER. Mr. PICKARD, who is a member of the linseed oil committee, said that the committee had been working on the question of how much foots was allowable, but that the laboratory in which the work was being done had been destroyed by fire. Mr. GARDNER cited a case in which the moisture in the foots of a high-foots linseed oil had prevented the paint from drying.

The Wednesday morning meeting was devoted to iron and steel. Professor HOWE, who presided, introduced Prof. A. L. VAN HECKE of the University of Louvain, Belgium, who made a few remarks and expressed his pleasure at being able to attend the meeting. Professor VAN HECKE is studying the latest developments in iron and steel in this country.

Four reports were read of committees A-1, A-4, A-5 and A-6, on "Steel" in general, "Heat Treatment," "Corrosion," and "Magnetic Properties," respectively. These reports were read by Messrs. C. D. YOUNG, ALBERT SAUVEUR, S. S. VOORHEES and C. W. BURROWS, respectively.

A paper was presented on "National Standard Specifications and Their Relation to Export Trade," by W. R. WEBSTER.

A paper on "Heat Treatment of Carbon Steel Locomotive Axles," by C. D. YOUNG, brought out considerable discussion as to the advisability of water quenching instead of oil quenching. The paper discussed results obtained with heat treatment of axles, using oil quenching in one case and water quenching in another. The results were favorable to water quenching.

A paper on "Recrystallization as a Factor in the Failure of Boiler Tubes" was presented by A. E. WHITE and H. F. WOOD. This was the result of an extensive and interesting piece of research work and is reserved for publication in a later issue.

Wednesday afternoon was devoted to recreation, and some of the members journeyed to the Northfield Country Club, where a golf tournament among the members of the society was in progress, and some of the sailing enthusiasts enjoyed this form of sport.

The Wednesday evening session was devoted to Tests and Testing. The report of committee E-1 on "Methods of Testing" was read by G. LANZA, chairman. A topical discussion on yield point and proportional limit was presented by J. E. HOWARD, T. D. LYNCH, H. F. MOORE and F. B. SEELY. It was agreed that the term elastic limit was better to use than proportional limit, and that the term yield point was vague and inexact. Curves

were shown of various steels showing a variety of ranges between the proportional limit and yield point, and it was urged that designers specify steel whose load would always fall well below the proportional limit.

Other papers presented were as follows: "An Apparatus for Determining Soil Pressure," by A. T. GOLDBECK and E. B. SMITH; "Endurance and Impact Tests of Metals," by D. J. MCADAM, Jr.; "Constants and Diagrams for Repeated Stress Calculations," by H. F. MOORE and F. B. SEELY; "Methods of Testing the Durability of Pipe Under Corrosion," by F. N. SPELLER. This paper is published in full on page 87 of this issue.

At this session a resolution was passed indorsing legislation to enforce the use of the Centigrade scale in Government publications after 1920. This is the first time the Society has acted on a legislative question.

The Thursday morning session was devoted to ceramics, road materials, and gypsum. The papers consisted mostly of committee reports.

A paper on "Practical Methods for Testing Refractory Fire Brick" was presented by C. E. NESBITT and M. E. BELL. In discussing this paper J. S. UNGER said it showed the importance of tests for bricks. The suggestion that tests be made more severe than actual working conditions in order to accelerate the tests is a radical departure from accepted practice. Failure of bricks is not due to one cause, but to a combination of several causes. Dr. Unger did not think that the rapid water-cooling used in the tests was comparable to air-cooling in practice. The results showed that some bricks are different at one end than at the other, and therefore show a non-uniformity of material. The most important parts of the paper are the curves showing the effect of water in making brick and the table showing the pressure effect. G. C. STONE confirmed the contention that denser brick was the better to use. He found that in testing brick it was impossible to get good slagging results except in actual practice. W. H. FULWEILER said the authors were to be congratulated for having the courage to break away from ordinary testing methods. He thought the results of using a ball as pressure medium against brick might not give the same results as a load spread over the whole brick. In tests made by him the removal of the outer skin caused irregularity in the results. R. C. PURDY said that he had found no laboratory test comparable to service tests. Publication in full of this paper is reserved for a later issue.

A smoker was held Thursday evening, at which a general good time was had.

The Friday morning session was devoted to non-ferrous metals. The report of Committee B-1 on "Copper Wire" was read by J. A. CAPP, chairman, and of Committee B-2 on "Non-Ferrous Metals and Alloys" was read by WILLIAM CAMPBELL, chairman. A paper on "Aluminum Bronze" was presented by W. M. CORSE and G. F. COMSTOCK. A paper on "Specifications for Brass Condenser Tubes" was presented by A. E. WHITE.

The Friday afternoon session was devoted to miscellaneous materials. The report of Committee A-3 on "Cast Iron and Finished Castings" and Committee D-6 on "Coke" were read by RICHARD MOLDENKE, chairman; the report of Committee D-7 on "Timber" was read by HERMANN VON SCHRENK, chairman. The following papers were presented: "Apparatus for Testing the Standard Cast-Iron Arbitration Bar," by H. L. MORSE; "Quantitative Test for Resistance of Lubricating Oils to Emulsification," by W. H. HERSCHEL; "Emulsification of Mineral Lubricating Oils," by P. H. CONRADSON.

The total registration was between 500 and 600, exclusive of about 150 ladies, for whom special features of entertainment were provided.

The Iron and Steel Market

The extreme dullness in the steel market has served to emphasize its underlying strength, for absolutely no selling pressure has been developed by the dullness, the mills all holding strictly to their former prices, while they do not offer materially earlier deliveries than they did a month ago. Instead of the market becoming dull at the beginning of July, as it usually does, it turned dull about the beginning of June, and thus a fair test has been afforded.

The mill position as to actual orders in hand makes a very strong showing. The United States Steel Corporation is stated to have 6,000,000 tons of actual shipping orders in hand, in a total of about 10,000,000 tons of unfilled obligations, showing not only a very large tonnage but a very high proportion of obligations in the form of specifications. The other large interests are assumed to be in substantially the same position.

The disclosure of such a strong mill position has caused sentiment to become much more hopeful as to the more distant future of the steel market. Hitherto the general opinion has been that the course of the market would be simply one of the orders in hand being filled, together with such orders as drift in from time to time when there is no general buying movement, and that thereafter there would be a general readjustment, with a period of lessened mill activity and a reduction in prices. Now, however, the expectation is entertained in some quarters that next fall another buying movement will be inaugurated, without any readjustment in prices, whereby the period of full activity would be prolonged well into 1917 at least. This would be an unprecedented course, for hitherto no general buying movement in steel has started at the price level at which the preceding movement left off, it being conventional for prices to decline between buying movements, but, of course, all conditions are abnormal at this time.

Export Demand

The demand for shells and shell-steel, instead of being satisfied by the recent heavy buying, has continued to date, France and Italy being now in the market in a large way, and for deliveries through the first quarter of the new year. Various reports have been given circulation, chiefly in stock market circles, that munition business is declining, but these reports are not confirmed in steel circles and appear to have been promulgated for an ulterior purpose. Indications are that the production of shell steel will be greater in the second half of the year than in the first half.

The demand from the allied belligerents for classes of steel incident to the prosecution of war, other than shell steel, is very insistent, covering railroad material of all descriptions as well as ship steel. Many weeks ago Russia inquired for 350,000 tons of rails, and shortly placed somewhat more than half the tonnage with the Steel Corporation, but great difficulty has been experienced in arranging deliveries with the independents for the remainder. Bessemer steel rails have been offered, but apparently have not been accepted as yet. Russia is also inquiring in a large way for cars and locomotives.

The demand from neutral countries for steel products has continued heavy since the increase two or three months ago, and it seems probable that in the event of a decrease in domestic consumption the export business would readily take up the slack.

Finished steel prices are unchanged for forward delivery and no material change is expected for months in the important products. There has been a further diminution in the premiums asked for early deliveries of certain classes of material, and it is probable that

before long all premiums will have disappeared except on plates. The position in plates is a remarkable one, seeing that the regular mill price of 2.90c. is \$8 a ton above the regular price on shapes and bars, yet for early deliveries of plates a premium above 2.90c. regularly obtains.

Pig Iron

The condition noted in last report as to southern warrantors has been largely relieved, the warrantors that speculators were offering on the market at large cuts from the furnace price having been absorbed in major part. The furnace price has declined 50 cents to \$14, Birmingham, for early deliveries and the warrant market is on approximately the same basis. The northern markets have been decidedly quiet and some have shown a slight tendency toward weakness. The statistical position of pig iron is better than ever. There was a slight decrease in production in June, doubtless due to higher humidity, and the production in June, July and August promises to average less than in the preceding months, whereas the requirements of steel works promise to average more, as new steel making units are being completed from time to time and there is ample business to keep all capacity engaged. The scrap market, which had declined for three months and was exercising an unfavorable sentimental effect upon pig iron, suddenly turned strong the closing days of June and has since been advancing. Heavy melting steel has brought as high as \$17.25, delivered Pittsburgh, when a fortnight earlier it was difficult to sell at \$15.50. We quote: No. 2 foundry iron, delivered Philadelphia, \$19.75 to \$20.25; f.o.b. furnace, Buffalo, \$18.50 to \$19; f.o.b. furnace, Chicago, \$19; f.o.b. Birmingham, \$14 to \$14.50; f.o.b. Valley furnaces, 95 cents higher delivered Pittsburgh; Bessemer, \$21 to \$21.50; basic, \$18 to \$18.25; foundry and malleable, \$18.25 to \$18.50; forge, \$18 to \$18.25. Ferromanganese is much easier, prompt being frequently offered at as low as \$200, while there are reports of occasional concessions, for late 1917 delivery, from the regular contract price of \$175.

Steel

The billet market reflects great strength in the mill position. There is a heavy demand for export steel, as export demand goes, but a very light demand for domestic consumption, and that only for the earliest delivery, and the total demand is thus far from large, yet mills are very stiff in their views, frequently refusing to quote at all. Soft open-hearth steel is usually quoted at \$45, slight concessions from this price being made occasionally. Bessemer is nominally about \$43, but as a matter of fact demand for Bessemer is so light that no definite market is developed and any considerable demand might find the mills unable to quote. Discard and rejected steel, arising in the manufacture of shell steel, is less of a factor in the market, not because there is less of it but because the mills have found the market can absorb only so much of such special steel, and what they can sell they are selling in more orderly fashion, no matter how much may be left to be disposed of later, by sale as merchantable steel or by consumption as scrap.

The Non-Ferrous Metal Market

Monday, July 10.—The non-ferrous metals have continued generally dull during the last two weeks. The trust price of lead was reduced \$10 per ton, which was rather unexpected. Spelter continues its weakness.

Copper.—Copper has held fairly steady for a long time in spite of continued dullness. This has been due to the sold up condition of the market. Last week

some recessions were made, although declines were very slight. Producers ask 26c. to 27c. for fourth quarter electrolytic. Second hands offer prices slightly lower. For earlier deliveries prices ranging from 26c to 28c. are asked. The production in June is estimated at 200,000,000 lb., the exports amounting to 40,000 tons. According to estimates, the exports in the first half of the year were 145,000 tons, which is 7000 tons greater than the same period in 1915.

Tin.—Spot tin has been easy on heavy offerings, and is now quoted at about 39 $\frac{1}{2}$ c. The deliveries to consumers in June were 6398 tons, which is a record-breaking amount. Futures remain very firm, and there is only a difference of $\frac{3}{4}$ c. between spot and December deliveries. Straits tin for July delivery is quoted at 39c. with August at 38 $\frac{3}{4}$ c., September at 38 $\frac{1}{2}$ c., October at 38 $\frac{1}{2}$ c., and November at 38 $\frac{3}{8}$ c.

Lead.—The American Smelting & Refining Company reduced its price of lead to 6.50c., New York, on July 5. It was not expected, as business in lead was improving. This reduction has unsettled the market, and consumers are not buying to any extent. Independents also reduced their price to 6.45c., New York, following the trust reduction. Foreign and domestic buying was good up to July 5, considerable lead going to Russia and England.

Spelter.—Spelter continues to decline on further weakness and dropped below 10c. last week, for the first time since April of last year. Futures are stronger, and third quarter is quoted at 9c. and fourth quarter at 8c. The London spot market has also declined, and this has further depressed our market.

Other Metals.—Antimony has not touched bottom yet, and is offered at from 16c. to 17c. The market is weak and dull. Aluminum has declined slightly, and is now quoted at 60c. to 62c. Quicksilver is offered at \$80 per flask, with platinum at \$80 per oz. Silver is quoted at 62c.

Presentation of the Franklin Medal to Theodore W. Richards

At a meeting of the Franklin Institute of Philadelphia, held on May 17, 1916, the Franklin Medal was presented to Dr. THEODORE W. RICHARDS, professor of chemistry at Harvard University, and to Dr. JOHN J. CARTY, chief engineer of the American Telephone and Telegraph Company, while the Elliott Cresson Medal was presented to the American Telephone and Telegraph Company, THEODORE N. VAIL, president.

Dr. HARRY F. KELLER, for the Committee on Science and Arts of the Franklin Institute, made the presentation speeches. He pointed out that accordance to the wishes of the founder, Samuel Insull, the Franklin Medal is "awarded from time to time to those workers in physical science and technology, without regard of country, whose efforts, in the opinion of the Institute, have done most to advance our knowledge of physical science and its applications."

In reviewing Dr. Theodore W. Richards' work, Dr. Keller spoke in part* as follows:

In spite of the vast expenditures for their armies and navies in times of peace, the governments of European countries have long realized that liberal appropriations to their institutions of learning and for the promotion of scientific research is money well invested; in our country, on the other hand, the endowment of universities and research laboratories is largely dependent upon the munificence of private individuals. Nevertheless, the advancement of science in American laboratories, and by American workers, especially in recent years, has been quite abreast of that

*The complete report of all speeches may be found in the July issue of the *Journal of the Franklin Institute*, pages 6 to 14, from which this account is taken.

in European countries; and in not a few branches of science we are proud to point to our compatriots as the peers of those abroad.

The eminent chemist who is to receive the Franklin Medal is a striking case in point. Though still in the prime of life, and looking forward, perhaps, to even greater achievements, his contributions to chemical science are universally recognized as second to none, either in number or importance, made by any contemporary investigator. Only recently the Nobel Prize of 1914 in chemistry was awarded to him, and the oldest and most famous institutions of learning in every part of the world have fairly showered upon him their highest honors and distinctions. More than a dozen universities have conferred upon him their honorary degrees; learned societies, both here and abroad, have vied with one another in electing him a member or officer; and the most highly prized trophies of chemistry, such as the Davy, the Faraday, and the Willard Gibbs Medals, have been bestowed upon him. With the award of the Franklin Medal the last great link in this great chain of honors would seem to be added.

And it seems peculiarly appropriate that this should be done in his native city. He was born in Germantown, in

THEO. W. RICHARDS

1868, the son of a well-known painter of landscapes and marines. It was there, also, that he spent most of his childhood, and where his gifted mother conducted his early education. His curiosity and interest in experimentation and science were early awakened by friends of the family, among them Dr. John Marshall of the University of Pennsylvania. At the age of fifteen he entered the Sophomore class at Haverford College, where he first seriously studied chemistry under Dr. Lyman B. Hall. After graduation in 1885, he studied Greek and entered the Senior class in Harvard, as its youngest member, in the autumn of the same year.

Since then his career, with the exception of a few and comparatively short interruptions, has had its scene in Harvard University. Graduating as A. B. in 1886, *summa cum laude*, with highest honors in chemistry, he received a fellowship in the graduate department and conducted research work under Josiah Parsons Cooke, taking the degrees of A.M. and Ph.D. in 1888. The following year he spent in Europe, visiting eminent chemists and important laboratories in various countries, and familiarizing himself with special methods of analysis and research. Returning to Harvard in 1889, he was appointed assistant, and from this position he gradually rose to that of Professor of Chemistry and Director of the recently founded Wolcott Gibbs Memorial Laboratory.

The only prolonged absences from Harvard were for the purpose of studying with some of the German masters, and, in 1907, when he was selected as Visiting Professor to the University of Berlin. Teaching a group of advanced students his methods of experimentation and research, he made a profound impression on both the students and professors. It was little short of a revelation to the German chemists that the time had arrived for reciprocity between the American and German universities in the teaching of the most advanced thought and practice in chemical research.

To sketch and characterize the work of our metallist in a few sentences—and that is all I can here attempt to do—is a difficult, an almost hopeless, task. If you consider

that ever since he graduated from Harvard in 1886 he has continuously and indefatigably been active as a teacher and investigator; that his fertile brain has planned and directed the work of great numbers of assistants and students; that his contributions to science extend over vast domains of inorganic, physical, analytical, and theoretical chemistry, and in many cases far beyond the border-line of physics; if you consider how numerous, divergent, and extended are the paths he has traveled, you will understand that only a very few of the high lights can here be pointed out.

Best known and, in certain respects, most important, are the researches on the atomic weights of more than twenty of the chemical elements. These elements were not chosen at random, but very carefully selected with a view to solve chemical problems of fundamental importance. The papers published on this work extended over many years, and must be counted among the classics of chemical literature. They reveal the masterly reasoning of the author, his fertile scientific imagination, his resourcefulness and skill as an experimenter. They abound in the description of new observations, new methods, and new forms of apparatus. The atomic weights themselves are determined with the utmost precision that the resources of modern science permit.

It was from the investigation of the fundamental properties of the elements that most of his other researches took their starting-points. Among them are the studies of the compressibility of elements and compounds; of the changes in atomic volume; of the birth of crystals as revealed by micro-photography and the kinetoscope; of thermochemical, electrochemical, and, lately, also of radiochemical problems. His hypotheses concerning the sour taste of acids and the compressibility of atoms are noteworthy contributions to theoretical chemistry, and he has also devised one of the best methods of teaching elementary chemistry.

As, due to illness, Dr. Richards was unable to be present, the president announced that the medal and accompanying certificate would be forwarded to him. Dr. George A. Hoadley then read the following address for Professor Richards:

The Essential Attributes of the Elements

BY THEODORE W. RICHARDS

We come together to-day, in this world-renowned Institute, founded in honor of one of the greatest of our countrymen, to participate in an annual celebration of progress in pure and applied science. Franklin himself would have heartily approved of such an annual celebration; he was deeply interested in the study of Nature, and profoundly convinced of the importance to humanity of exact knowledge and its practical application. Inspired by his conviction of the usefulness of science, he founded here in Philadelphia the oldest American scientific society, and here he performed the first significant experiments in physics of the New World. He would have eagerly supported the Institute in its aims and activities, and he is fittingly commemorated in its name.

To be included in this celebration of scientific advance in the home of Franklin, my own native city, is a privilege; and I beg to express my hearty appreciation of the very great honor which the Institute has conferred upon me.

As the title on the program indicates, my pleasant duty now is to speak to you on the fundamental properties of the elements, which have formed the chief subject of my chemical and physical studies. At the outset one may well ask: What are the elements, and what shall we designate as their fundamental properties? In these iconoclastic days several of our old scientific idols seem to have been shattered. If uranium and radium are only transitory, may not the other so-called "elements" also be slowly decomposing? In this case, ought we to count them as elements at all? Moreover, if, as some suppose, the atom is made up of nothing but electrons (positive and negative), what has become of the old atomic theory?

These questions, disturbing although they may seem

to be, are easily answered. Perhaps, from a philosophical and etymological point of view, the chemical atom no longer deserves its name; but the fact remains that in all the ordinary affairs of life our relations with the chemical elements primarily concerning us are unchanged by all the fascinating new knowledge. These same old elements remain as permanent as they ever were; and the only satisfactory explanation of the definite proportions by weight in which they combine is now, as of yore, the assumption of ultimate, undestroyed (if not indestructible) particles or chemical "atoms." The atomic theory is indeed even more convincing today with regard to mundane chemical affairs than it was before the dawn of radio-activity.

Of course, no one pretends nowadays that the chemical elements are to be considered as absolutely incapable of decomposition. Even supposing, however, that in the hottest stars some of them disintegrate, on earth, at least, they are amazingly permanent. It is concerning the earthly chemical elements, therefore—the old-fashioned kind of half a century ago—that I have to speak.

These elementary chemical substances build up everything about us, as well as our own bodies. It has always seemed to me, therefore, that the fundamental attributes which determine their behavior are worthy of very careful scrutiny.

Among the most fundamental of attributes, if not the most significant of all, is the tendency possessed by the elements to combine in definite proportions by weight. This we explain, as already stated, by the assumption that all matter is made up of atoms. One cannot believe that these atoms should have anything so important as their weight decided by mere chance or accident. Therefore, I chose the study of the atomic weights as the first of the fundamental properties to be investigated, and perhaps half of my time during the last thirty years has been devoted to this subject.

Great accuracy in the work was sought for several reasons, the most important of which was an earnest desire to find if possible the suspected mathematical relationship between these fundamental quantities. Such a relationship, if discovered, would greatly deepen our insight; and if it is to be found the data to be compared must be determined as accurately as possible.

Another reason for taking great pains in determining atomic weights is the fact that these figures are used by chemists throughout the world in their daily work oftener than any other series of data. All the manifold happenings of Nature occur in material built up of these same atoms. If we are to analyze or synthesize, or in any way have to do with the quantitative relations of reacting chemical substances under any circumstances, we must ultimately turn to the atomic weights for help. It is not too much to say that the atomic weights are the basis of quantitative chemistry.

More than two thousand years ago Plato said: "If from any art that which concerns weighing, measuring and arithmetic is taken away, little remains of that art." To-day we may paraphrase this saying as follows: "If from chemistry are taken away the atomic weights (or other numerical data representing the same definite proportions), little will remain of that science." As a science becomes more scientific it becomes more quantitative, and greater accuracy in the determination of its fundamental mathematical basis is required.

There is not time this afternoon to go into the details of many determinations of nearly thirty atomic weights carried out during as many years at Harvard. The effort was made to build upon the basis provided by the careful work of Berzelius, Marignac and Stas, with the help of the new discoveries in physical chemistry concerning solubility, hydrolysis, adsorption, and solid solu-

tion. Metals were compared, as to their combining proportions, especially with chlorine, bromine and iodine; moreover, many other careful comparisons likewise were made, as, for example: oxygen with silver through lithium chloride and lithium perchlorate; silver into nitrogen and sulphur through silver nitrate and sulphate; oxygen with carbon and sulphur sodium carbonate and sulphate, and many others. These, taken together, tend to put our whole table of atomic weights upon a stabler basis. The elements of which the atomic weights have been determined under my own immediate supervision are the following: copper, barium, strontium, calcium, magnesium, zinc, nickel, cobalt, iron, uranium, cesium, sodium, potassium, chlorine, nitrogen, silver, sulphur, carbon, lithium and radio-lead. To these should be added, as part of the Harvard contribution, those studied by my most energetic pupil in this line of work, Prof. G. P. Baxter, long since an independent investigator on his own account: arsenic, bromine, cadmium, chromium, iodine, lead meteoric iron and nickel, manganese, neodymium, praseodymium, and phosphorus. The most interesting outcome of my work is perhaps the discovery that lead from radio-active minerals possesses an atomic weight distinctly less than that of ordinary lead—206.1 instead of 207.2—although it gives the same spectrum.

If I were to sum up in a few words the lessons of these protracted investigations, I should be inclined to say that the secret of success in the study of atomic weights lies in carefully choosing the particular substances and processes employed, and in checking every operation by parallel experiments so that every unknown chemical and physical error will gradually be ferreted out of its hiding-place. The most important causes of inaccuracy are: the solubility of precipitates and of the material of containing vessels; the occlusion of foreign substance by solids, and especially the presence of retained moisture in almost everything. Each of these disturbing circumstances varies with each individual case. Far more depends upon the intelligent choice of the conditions of experiment than upon the mechanical execution of the operations, although that, too, is important. I have often quoted the innocent remark which has occasionally been made to me: "What wonderfully fine scales you must have to weigh atoms!" and have endeavored to point out that the purely chemical work, which precedes the introduction of the substance into the balance-case, is much more important than the mere operation of weighing.

Laboratory work alone can furnish us with accurate values of the atomic weights. No speculative method involving higher mathematics has as yet been able to solve definitively the cosmic puzzle of their relative magnitudes. In this direction, as in many others, chemistry is still largely an inductive science. When we have discovered the realities, we shall be in a position to attempt to explain them. In the meantime more accurate views, discovered little by little through patient investigation will be of use to the thousands of men throughout the world who daily employ these fundamental data of chemistry.

Matter possesses not only the fundamental properties of weight and mass, measured (from the chemical point of view) by the combining proportions of the elements, but also an equally fundamental attribute which causes it to occupy space. Thus, side by side with the study of weight and mass, the study of volume deserves close attention. This latter property is more changeable and more puzzling in its varied manifestations than the constant attributes of weight and mass. Almost every solid expands, occupying more space as it is heated, expands yet more in the act of melting, and finally

swells up into an altogether disproportionate volume when it is converted into vapor. In each of these states of matter the application of pressure produces a lessening of the volume—very small, but still perceptible in the case of solids, usually greater in the case of liquids, and still very much greater in the case of gases. The behavior of gases is very similar in each case: here the molecules must be far apart. On the other hand, solids and liquids behave in a manner entirely different from gases and entirely different from one another. The molecules must be very near one another, and the specific nature of each must come greatly into play. Even for any single substance the space-filling relations of the solid and liquid form are highly complex, and when comparison is made between different substances the complexity is vastly increased; yet none of these varying manifestations of the property of occupying space can be accidental. Each must have its inner significance, and the relation of each to the other cannot but be fundamentally connected with the ultimate nature of the substance concerned. Some of the relations are opened to us by the science of thermodynamics; but many of the data must be found, like the atomic weights, by experiment alone.

These considerations led me, nearly twenty years ago, to begin the study not only of the space occupied by the elements, especially in their liquid and solid states of aggregation, but also of many other related fundamental properties of the elements and their compounds, including the effect of increasing temperature and increasing pressure. Some of the data needed in this study had already been provided by the preceding work of others, but particularly in the case of compressibility, of which I wish especially to speak, very few data had been gathered even as recently as fifteen years ago. Only three or four elements had been carefully studied, and these by methods of doubtful efficacy. Hence the first step was to devise a simple and accurate method capable of determining the exceedingly small compressibilities of the solid elements. This method was devised in 1903, and with its help the compressibilities of nearly forty elements have been determined with sufficient accuracy to trace with some precision their relations to one another and to the bulk occupied by these same elements. Bridgman has since carried the determination of a few of these to much higher pressures.

The outcome is highly interesting. If the elements are arranged in the order of their atomic weight, we find that the compressibilities show a very well-marked alternating periodic increase and decrease as the atomic weight progresses. This fluctuation parallels in remarkable fashion the periodicity of the atomic volumes noticed long ago by Lothar Meyer. It appears that when an element has a large atomic volume (that is to say, when the bulk occupied by its atomic weight in grammes is large) the compressibility also is large, and *vice versa*; and the changes are of the same order in the two cases. That these two properties are fundamentally connected no one can doubt after studying the parallel curves showing their similar progression with increasing atomic weight. Neither can one doubt that in the tracing of this parallelism a real step has been made in the study of the nature of the element.

Other properties, more or less related, also have been shown to have analogous rhythms.

One may well ask: Can any conceivable interpretation be found for such parallel rhythms, analogous to Dalton's interpretation of the combining weights of the elements? In other words, can we refer effects concerned with the space occupied by gross matter to the atoms themselves, somewhat as the combining proportions of the elements are referred to the weights of the atoms? It seems to me that this can be done.

If one assumes that the practical bulk of the atoms in solids and liquids is compressible, most of these results fit naturally into their expected places. Those atoms which are much distended (that is to say, have large atomic volume) would be expected to be the most compressible. We should expect also to find that increasing chemical affinity, by pulling the atoms more and more together, would likewise cause compression and, therefore, diminish volume; and cohesive affinity would have the same effect. There is much evidence to show that this interpretation is a reasonable one, but time forbids again that the details should be entered into here. The hypothesis is pragmatic; it considers, not the hypothetical space which may or may not be occupied by an imaginary center or core in the atom, but rather the space which the atom actually requires in solids and liquids. That this space is definite and significant is proved beyond cavil by such curves as those to which I have referred, as well as many other facts concerning solids and liquids. One may well hope that the combined following of this trail may lead one to heights from which a broader view of the materials constructing the universe may be obtained. But even if the hypothesis should some time be found wanting, it has served already a purpose helpful to progress, for it has stimulated many researches leading to the acquisition of new facts. These will stand in the future, whatever may be the fate of the theory.

Do these investigations concerning ultimate properties of things and these hypotheses concerning the correlation of the properties seem to be remote from the pressing problems of humanity? Not so. We must remember that applied science follows in the footsteps of theoretical science. The laws of chemistry cannot be adequately applied until they have been discovered. Only by researches delving into the hidden secrets of Nature by some such processes as these can new discoveries in the realm of pure science be made; and no one can tell how great may be the gain to the philosophy of Nature, as well as to the daily lives of men.

The vital importance of chemistry to modern civilization is well known to this distinguished audience. Someone has wisely remarked that, whereas the nineteenth century was primarily devoted to advance in mechanical and electrical directions, the twentieth century bids fair to be an essentially chemical century. In war—now, alas! devastating the earth—as well as in the lasting peace for which we hope, chemistry is bound to play an all-important part. We perceive that every manufacture is concerned with chemical substances; we realize that recent chemical discoveries have revolutionized the preparation of many things essential to our life and have initiated entirely new industries of great importance and benefit to mankind. The great war has only intensified our appreciation of these facts. We recognize also that even we ourselves, so far as our material existence is concerned, are chemical machines, and that our every thought and act is intimately bound up with chemical reactions, without which neither thought nor act could come into being. Let us hope that the triumphs of chemistry in the future will be used not only for furthering manufacture and agriculture, thereby rendering life more comfortable and prosperous; but, also, above all, for advancing hygiene and medicine to a point where the physician will be able really to understand the complex anomalies which confront him every day. Let us hope, too, that with this practical progress may be united the growth of a broader and saner philosophy of Nature, founded upon a truer knowledge of the materials composing the universe and of the energy which animates it. To such ends, full of blessing to humanity, let us dedicate the science in the future.

The Dyestuff Tariff Before Congress

When in our issue of April 15, 1916 (page 407), we commented on the defeat in the Senate of the Lodge dyestuff tariff amendment to the sugar bill, we remarked that it seemed unbelievable that this should be the end of the dyestuff tariff fight in the present Congress, and that we preferred to take it as part of the political game. This view has proven true. The dyestuff tariff fight has been renewed, and the game is on again, through the action of the Ways and Means Committee.

The new general revenue bill of the Administration, now before Congress, contains besides provisions for an increased income tax and for a tax on gross receipts from the sale of munitions of war, also a provision for the creation of a tariff commission, as proposed in the recent bill offered by Mr. Rainey of Illinois, further an anti-dumping clause, and a new dyestuff tariff.

The anti-dumping clause reads as follows:

"That it shall be unlawful for any person importing or assisting in importing any article from any foreign country into the United States to commonly and systematically sell or cause to be sold such articles within the United States at a price substantially less than the actual market value or wholesale price of such articles, at the time of exportation to the United States, in the principal markets of the country of their production, or of other foreign countries to which they are commonly exported, after adding to such market value or wholesale price freight, duty and other charges and expenses necessarily incident to the importation and sale thereof in the United States.

"Provided, that such act or acts be done with the intent of destroying or injuring an industry in the United States or preventing the establishment of an industry in the United States, or of restraining or monopolizing any part of the trade or commerce in such articles in the United States.

"Persons convicted of violating this provision are punishable by a \$5,000 fine or one year's imprisonment or both. Any person injured by violations may sue the defendant and recover threefold damages sustained and costs."

The proposed new dyestuff tariff is as follows:

"Sec. 400. That on and after the day following the passage of this act, except as otherwise specially provided for in this title, there shall be levied, collected and paid upon the articles named in this section when imported from foreign countries into the United States, or into any of its possessions, except the Philippine Islands and the islands of Guam and Tutuila, the rates of duties which are prescribed in this title, namely:

"Free List—Group I. Acenaphthene, anthracene, benzol, carbazol, cresol, cumol, fluorene, methylantracene, methylnaphthalene, naphthalene, pyridin, quinolin, toluol, xylol, crude coal tar, pitch of coal tar, dead or creosote oil, anthracene oil, all other distillates which on being subject to distillation yield less than 5 per centum of tar acids in the portion of distilling below 200 deg. C., and all other products that are found naturally in coal tar, whether produced or obtained from coal tar or other source, and not otherwise specially provided for in this title, shall be exempt from duty.

"Dutiable List—Group II. Amidonaphthol, amidophenol, amidosalicylic acid, aniline oil, aniline salt, anthraquinone, binitrobenzol, binitrotoluol, binitronaphthalene, binitrochlorobenzol, benzaldehyde, benzylchloride, benzidin, chlorophthalic acid, cumidin, dianisidin, dimethylanilin, dioxynaphthalene, diphenylamin, methylanthraquinone, metanilic acid, nitrobenzol, nitrotoluol, nitronaphthalene, nitraniline, nitrophenylenediamine, nitrotrouenediamine, naphthylamine, naphthol, naphthylenediamine, phenol, phthalic acid, phthalic anhydride,

phenylenediamine, phenylnaphthylamine, resorcin, salicylic acid, sulfanilic acid, toluidin, tolidin, tolylenediamine, xylidin, or any sulfoacid or sulfoacid salt of any of the foregoing, all other distillates which on being subjected to distillation yield 5 per centum or more of k.r. acids in the portion distilling below 200 deg. C., and all other products obtained, derived or manufactured in whole or in part from the products provided for in Group I, all the foregoing not colors, dyes or stains, photographic chemicals or explosives, and not otherwise provided for in this title, 15 per centum ad valorem.

Group III. All colors, dyes or stains, whether soluble or not in water, color acids, color bases, color lakes, photographic chemicals or explosives, not otherwise specifically provided for in this title, when obtained, derived or manufactured in whole or in part from any of the products provided for in Groups I and II, including natural alizarin and indigo, 30 per centum ad valorem.

"Sec. 401. That on and after the day following the passage of this act, in addition to the duties provided in Sec. 400, there shall be levied, collected and paid upon all articles contained in Group II a special duty of 2½ cents per pound, and upon all articles contained in Group III (except natural and synthetic alizarin and dyes obtained from alizarin, anthracene and carbazol; and natural and synthetic indigo and all indigoids, whether or not obtained from indigo), a special duty of 5 cents per pound.

"During the period of five years, beginning five years after the passage of this act, such special duties shall be annually reduced by 20 per centum of the rate imposed by this section, so that at the end of such period such special duties shall no longer be assessed, levied or collected; but if at the expiration of five years from the date of the passage of this act the President finds that there is not being manufactured or produced within the United States as much as 60 per centum in value of the domestic consumption of the articles mentioned in Groups II and III of Sec. 400, he shall by proclamation so declare, whereupon the special duties imposed by this section on such articles shall no longer be assessed, levied or collected.

"Sec. 402. That paragraphs 20, 21, 22 and 23 of Schedule A of Sec. 1 of an act entitled 'An act to reduce tariff duties and to provide revenue for the government, and for other purposes,' approved Oct. 3, 1913, and paragraphs 394, 452 and 514, and the words 'carbolic' and 'phthalic' in paragraph 387 of the 'free list' of Sec. 1 of said act, and so much of said act or any existing law or parts of the law as may be consistent with this title are hereby repealed."

To understand clearly the scope of the proposed new dyestuff tariff of the *Kitchin bill* just quoted, it must be compared with the *Underwood tariff*, now in force since 1913, and with the proposed *Hill bill*, based on the recommendations of the chemical and dyestuff committee of the New York Section of the American Chemical Society, of which full details were given in our issues of December, 1914, Vol. XII, page 753, and Feb. 1, 1916, Vol. XIV, page 125.

From present developments it is evident that without exception everybody agrees that the rates of the Underwood tariff are absolutely insufficient. It provides a duty of 30 per cent ad valorem on aniline dyes and 10 per cent on intermediates, alizarin and anthracene dyes and indigo are free. There is no surtax per pound on anything.

The Hill bill represents what would be needed for such purpose according to the unanimous convictions not only of the present American dye makers, but of the American chemical industry in general.

The Kitchin bill introduces a new and very interesting feature into tariff matters by proposing a time limit (second paragraph of Sec. 401 quoted above). But it differs from the Hill bill also in two other points.

Firstly, with respect to the intensity of protection (value of duty), the Hill bill places a duty of 15 per cent ad valorem on intermediates and 30 per cent on finished dyes; the Kitchin bill does the same. But in addition to this, the Kitchin bill adds a "special duty" of 2½ cents per pound on the intermediate and 5 cents per pound on finished dyes, while the Hill bill provides for 3¾ cents per pound on the intermediates and 7½ cents per pound on finished dyes. Thus the amount of the special duty considered necessary by the chemical industry according to the Hill bill is reduced in the Kitchin bill by 33 1/3 per cent.

Secondly, with respect to the width or extension of the protection, the Hill bill tries to protect the new dyestuff industry all around. The Kitchin bill does not, as it exempts alizarine, anthracene and indigo from the additional "special duty" (Sec. 401, first paragraph).

Other matters have naturally come up, such an appeal to place an equal duty on coal-tar medicinals as on dyestuffs. Without entering into a discussion of the fairness of such a proposal, we do not think it likely that the present Congress will do much more than decide between the Kitchin bill and the Hill as they stand. On what we believe are the principal points to be considered in reaching this decision we comment on our first editorial page.

Metallurgy in Ontario

The annual report of Arthur A. Cole, engineer for the Ontario Government Railway, on the mining industry in northern Ontario during 1915, has just been issued. As usual, it contains an unusual amount of interesting information and data on mining and metallurgy in the remarkable Cobalt and Porcupine districts. Ontario is now the largest gold and silver-producing Province in Canada, yielding 44 per cent of the gold and 87 per cent of the silver. The increased cost of supplies during 1915 was partly compensated by the increased price of metals, but the greatest compensation came in the way of improvement in the work whereby costs per ton were materially reduced. The following comparative statement of the cost of milling supplies used at Cobalt will give an idea of the increase that has taken place:

Material	Ante-Bellum	March, 1916
Alumina dust, lb.	\$0.34-\$0.38	\$0.75-\$0.90
Caustic soda, 100 lb.	1.30	7.50
Chromosulphic acid, 100 lb.	4.16	7.58
Cyanide-sulphate, lb.	0.15	0.16
Cyanide-sulphate, lb.	0.15	0.20
Mercury, 75 lb.	37.00	200.00-300.00
Pebbles, Fresh, ton f.o.b. New York	9.75	13.25
Pebbles, Danish, ton f.o.b. New York	13.00	15.00-16.00
Sulphuric acid, 100 lb.	1.27	3.90
Sulphuric acid, 100 lb.	1.30	1.95
Zinc dust, lb.	0.065	0.38-0.35

At Porcupine, which is about 100 miles northwest of Cobalt, still higher prices have prevailed and advances of from 8 per cent to 427 per cent in the cost of mill supplies is recorded.

Porcupine continues to be the principal gold-producing camp, and the output for 1915 was valued at \$7,580,766, as against \$5,203,229 for 1914. Cobalt is the main source of silver, having produced 234,000,000 ounces since its discovery in 1904. The output for 1915 was 23,653,713 ounces, a decrease from the previous year when the output was 25,162,841 ounces. The production of silver from Cobalt has constantly decreased since

1911, when the high point of 31,507,791 ounces was reached. There were nine companies at Cobalt, each of which produced more than one million ounces of silver during 1915. Dividends and bonuses paid by Cobalt companies in 1915 amounted to \$4,523,415; the grand total since the discovery of the camp is \$57,614,202.

A number of Cobalt companies are now employing the flotation process. The largest plant is that of the Buffalo company, which experimented first with a 50-ton plant of the Callow pneumatic type. A permanent plant of 600 tons capacity is now being erected for the treatment of 500 tons per day of accumulated tailings from water concentration and of 100 tons of mine rock. The fine-grinding equipment will consist of four 5 ft. 6 in. by 20 ft. tube-mills, and the flotation plant of four two-compartment, triple-length Callow cells to be used as roughers and four standard two-compartment cells as cleaners. The old cyanide plant will be used for de-watering flotation concentrate and for the cyanidation of flotation middling. A flow-sheet of the flotation plant is herewith given.

The Vulcan Soot Cleaner Company has recently issued a catalog describing its product, the Vulcan soot cleaner. The catalog is nicely illustrated and the frontispiece is a four-color reproduction of actual specimens of soot from different boilers and with different fuels. The different sections of the catalog contain complete information as to what soot really is, and how it can be economically removed.

Potash in British Columbia.—The Canadian Potash and Algin Co. (Ltd.) was organized in 1915 and a plant established at Sydney, British Columbia. It is now utilizing from 30 to 40 tons of raw kelp daily in the manufacture of fertilizer, according to Commerce Reports. The product is a fine, dry, but heavy powder. Plans are being made to enlarge the plant and install special machinery for the extraction of other materials from kelp.

It is believed by the promoters of the industry in this Province that the manufacture of iodine and potash, without the production of by-products, would not prove very profitable in normal times, but the increase in the price, especially of potash, on account of the war, will enable the British Columbia company to include these and other by-products in the output of the factory at Sydney.

Algin, which will be made one of the specialties of the local plant, is said to possess a viscosity many times greater than that of starch or gum arabic. The chief use of algin is for the sizing of fabrics, the effect being to give the material treated the appearance of waterproof sheeting, but leaving it more elastic than when treated by other customary waterproofing materials.

Catalysis in the Formation of Gasoline from Kerosene

BY GUSTAV EGLOFF AND ROBERT J. MOORE

In the formation of gasoline from heavier petroleum oils three distinct methods may be recognized:

1. THE TWO-PHASE SYSTEM, GAS AND LIQUID.
 - a. Distillation in an ordinary still at atmospheric pressure.
 - b. Distillation under greater than atmospheric pressure.
2. THE ONE-PHASE SYSTEM, GAS.
 - a. The cracking takes place at atmospheric pressure.
 - b. The cracking takes place at greater than atmospheric pressure.
3. THE THREE-PHASE SYSTEM, GAS, LIQUID AND SOLID.

The dissociation of the heavier hydrocarbons into lighter hydrocarbons takes place by the use of catalytic and chemical agents.

Of the three methods the two-phase system is the oldest. In this system there is always present liquid oil in the still in equilibrium with the oil gas above the liquid layer. Silliman¹ in 1855 predicted that in ordinary distillation of heavy oils decomposition takes place, giving lighter oils. Since that time various processes have been devised for the production of the more valuable oils as the particular uses of the times called for. Before the advent of motor cars the production of kerosene was important, at present gasoline has become the primary product. The most important process now for the increased production of gasoline is the Burton.² This is a gas-liquid system under a pressure of approximately seventy pounds. Other important processes of the first mentioned type are those of Brooks, Bacon & Clark,³ and Snelling.⁴

THE GAS-PHASE METHOD

The gas-phase method has come rapidly to the fore in the past few years. This system is fundamentally different from the foregoing one in that no liquid is present and only the vaporized oil is cracked. Not much has been done with this system, however, at atmospheric pressure due to the highly unsaturated aliphatic formation and low yields of gasoline.⁵

The gas-phase method under pressures greater than atmospheric has been thoroughly worked out by Rittman.⁶ He has thermolized paraffin, paraffin-asphaltic and asphaltic base petroleum, kerosene, gas oils and fuel oils in the gaseous phase under pressure.

THE THREE-PHASE METHOD—GAS, LIQUID AND SOLID

In the use of catalysis for the conversion of heavy oils to light boiling fractions a number of metals and their chlorides have been tested. Those usually adopted for their catalytic effect have been aluminium, zinc and magnesium.

The method usually employs anhydrous aluminium chloride or passes hydrogen chloride or chlorine over metallic aluminium in a still. In this reaction the solid phase, aluminium or its chloride, is in equilibrium with the liquid oil and the gas above it. Friedel and Crafts⁷ published in 1878 the findings that aluminium chloride gave in contact with heavy oils, oils of a much lower

volatility. G. W. Gray¹ in 1913 took out two process patents upon this idea as also did McAfee² in 1915. McAfee specifies the use of metals for the formation of gasoline, paraffin and lubricating oils from heavy petroleum. He describes the action of anhydrous aluminium chloride upon three type oils: paraffin, paraffin asphaltic and asphaltic base oils. By the use of anhydrous aluminium chloride the results given in Table I were obtained by him:

TABLE I

Paraffin base oil	100 c.c.	100 c.c.	100 c.c.
Paraffin asphaltic base oil	100 c.c.	100 c.c.	100 c.c.
Asphaltic base oil	100 c.c.	100 c.c.	100 c.c.

OBJECT

The formation of gasoline from the thermal and pressure decomposition of heavy oils in the gas-liquid condition has been thoroughly studied. Rittman's work upon the gas phase system of thermal and pressure decomposition of various oils for the production of gasoline has been inclusive. Contrasted with the work that has been done on the gas-phase and the gas-liquid system, comparatively little material can be found on the gas-liquid-solid system. It was with the view of getting more definite information on this latter type system that the following experiments were undertaken. Thus the effect of the catalytic or chemical action of the chloride of metals and non-metals upon gasoline formation from a paraffin base kerosene has been studied.

Experimental Procedure

The experiments were carried on in an 800-c.c. Kjehldahl flask fitted with a two-holed cork stopper. Through one hole was attached a Ginsky distilling head connected to a 24-in. Liebig condenser. Through the other hole a glass tube extended to the bottom. Through this was passed the hydrogen chloride gas generated in a Freas apparatus by dropping concentrated sulphuric acid on ammonium chloride. The gas was washed and regulated by a Dreschel wash bottle containing concentrated sulphuric acid. The chlorine used was generated by dropping concentrated hydrochloric acid on potassium permanganate.

A charge of 400 or 500 c.c. kerosene and 10 per cent by weight of the catalyst was placed in the Kjehldahl flask, which was made airtight with sodium silicate and collodion, and heated in each case with a uniform size Bunsen flame. The average time of reaction was three hours.

The distillate in each case was measured and washed in a separatory funnel with sodium hydroxide solution. The oils from the phosphorus and selenium runs gave a bad odor due to the formation of phosphine and hydrogen selenide. After taking its specific gravity, 100 c.c. of oil was distilled in a standard Engler 100 c.c. flask, the cut to 150 deg. C. being taken as gasoline.

The characteristics of the reaction and the appearance of the distillates differed widely in the various runs. The color and clarity of the residue left in the Kjehldahl flask varied all the way from a slight reddish tinge and insignificant red precipitate, in the case of selenium, to a black muddy sludge, in the case of aluminium. This sludge, which appeared in several of the runs, was partly volatile and condensed in the Ginsky head and condenser, and even came over into the distillate offering a certain amount of annoyance in clogging the apparatus. In the chlorine runs on phosphorus and sulphur the combination to form chlorides was so strongly exothermic that flashes of light were con-

tinually emitted under the oil and the system continued at boiling, even when the burner was removed.

OIL USED

The oil used in these experiments was a water white kerosene derived from a paraffin base Pennsylvania crude petroleum. The oil analyzed as stated in Table 2.

Experiments

With hydrogen chloride five different elements were used, sodium, magnesium, aluminium, zinc and selenium. With chlorine were used sulphur, selenium, phosphorus, silicon, aluminium and magnesium. With the exception of sulphur, phosphorus and sodium, which soon melted under the heated oil, the elements were used in a finely powdered form.

Discussion of the Data

Table 3 tabulates the analytical results of passing hydrogen chloride over the metals sodium, magnesium, aluminium, zinc and the non-metal selenium in the conversion of kerosene to gasoline. The per cent of oil

recovered, the specific gravity and distillation figures of the recovered oil are given. It is to be noted that aluminium chloride gives a specific gravity of 0.750 and the first drop from the end of the condenser at 31 deg. C., which gives an idea of the high volatility of the converted oil. The other metals and non-metal give gravities of the recovered oil ranging from 0.770 to 0.781 and the first drop from 182 deg. C. to 143 deg. C. The yield from aluminium and hydrogen chloride treatment of kerosene in the recovered oil is 52.5 per cent gasoline, whereas, the others range from 1.5 to 7.5 per cent. No satisfactory explanation is at hand why aluminium chloride should give such greatly increased yield of gasoline when compared to the chlorides of the other elements.

TABLE V—THE PER CENT OF GASOLINE UPON THE BASIS OF OIL USED FROM THE PASSING OF HYDROGEN CHLORIDE OVER METALS AND NON-METALS

	Magnesium	Selenium	Zinc	Sodium	Aluminium
Per cent gasoline.....	1.1	1.8	4.9	5.3	37.3

TABLE VI—THE PER CENT OF GASOLINE UPON THE BASIS OF OIL USED FROM THE PASSING OF CHLORINE OVER METALS AND NON-METALS

	Magnesium	Silicon	Sulphur	Phosphorus	Selenium	Aluminium
Per cent gasoline.....	0.3	0.6	0.7	1.7	5.3	15.9

Table 4 tabulates similarly to Table 3 the results of passing chlorine over the metals magnesium, aluminium, and the non-metals silicon, phosphorus, sulphur and selenium.

The specific gravity of the recovered oil from aluminium chloride treatment gave 0.778, with 62 deg. C. for the first drop. The chlorides of the other elements gave a specific gravity range of 0.780 to 0.796 and first drop between 134 deg. C. to 148 deg. C. The per cent of gasoline formation in the recovered oil for aluminium chloride was 21.5, and for the other chlorides between 0.5 to 11.0 per cent. Again the chloride of aluminium gave a much higher yield than the other chlorides.

A comparison of Tables 3 and 4 indicates clearly the higher yields of gasoline from the aluminium chloride formed by passing hydrogen chloride over the metal in comparison with its formation from chlorine. Excess of chlorine in the sphere of the reaction seems to inhibit somewhat the velocity of the reaction in gasoline formation from kerosene, whereas the hydrogen chloride excess increases the reaction velocity. Furthermore excess of hydrogen chloride reduces the unsaturated compound formation to a negligible amount in the gasoline fraction.

Tables 5 and 6 give the per cent of gasoline formation upon basis of the original kerosene used. Aluminium chloride formed from hydrogen chloride and aluminium gave 37.3 per cent, whereas using chlorine in its formation 15.9 per cent gasoline resulted. The per cent of gasoline from the chlorides of the other metals ranged between 0.3 to 5.3 per cent.

The Mechanism of the Reaction

As to whether the action of the chlorides of the metals or non-metals is simply that of an activator in the formation of low-boiling from high-boiling hydrocarbons, or whether addition compounds are formed which subsequently decompose into lower and higher volatility hydrocarbons is not definitely known as yet. The most likely mechanism of formation is by way of addition compounds of the chlorides with the hydro-

carbons of the starting oil. These addition compounds, not being stable at the temperature of the reaction, decompose into two or more compounds of the aliphatic group.

Perhaps the following hypothetical reactions will tend to make the addition and splitting off of the hydrocarbons clearer. In the kerosene oil, the paraffin hydrocarbons present are those with boiling points around Decane,¹⁰ Undecane, Tridecane, and higher molecular weight compounds. Let us take decane and undecane for our illustrative reaction of addition and decomposition:

In this assumed reaction the formation of hexane and pentadecane result with boiling points of 71 deg. C. and 270.5 deg. C. starting with decane B. P. 173 deg. C. and undecane 194.5 deg. C. Now in the reaction using the chloride of aluminium as catalyst, paraffins with boiling points around 71 deg. C. result when starting with an oil containing the compounds decane and undecane.

This illustration can be carried on so as to account for other hydrocarbons which are recovered in the gasoline. No unsaturated compounds were found in the gasoline fraction from the catalytic effect of passing hydrogen chloride over metallic aluminium. Unsaturation¹¹ was determined by absorption of the unsaturated compounds in sulphuric acid. The acid layer was water-white after shaking and allowing the two liquid layers to stand. But when chlorine was passed over the same metal, the gasoline fraction under similar treatment gave a deep reddish brown color in the acid layer, indicating clearly that unsaturated compounds resulted from this reaction. This brings us to the following hypothetical reaction of unsaturated compound formation:

The formation of amylene¹² and pentane would be indicated from this reaction. Gustavson's¹³ work is qualitative information in justification of the above assumed mechanism of reaction. He found that when a fraction of kerosene was treated with aluminium bromide and hydrogen bromide and then extracting the solution, the definite compound of aluminiumbromidebutylene $\text{AlBr}_3 \cdot \text{C}_4\text{H}_8$ was isolated.

SUMMARY

1. Three distinct methods for the conversion of heavy hydrocarbon oils into gasoline have been discussed. The single-phase gas system, the two-phase system of gas and liquid, and the three-phase system of gas, liquid and solid. The latter system has been treated in this paper.

2. Several hypothetical reactions have been shown to indicate the possible mechanism of reaction in the formation of low-boiling hydrocarbons from the action of aluminium chloride upon high-boiling point hydrocarbons.

3. The percentage of gasoline from kerosene due to the catalytic action of passing hydrogen chloride over the metals magnesium, zinc, sodium and aluminium gave the following results: magnesium 1.0 per cent, zinc 4.9 per cent, sodium 5.3 per cent, and 37.3 per cent for aluminium, all on the basis of the oil used.

4. The percentage yield of gasoline from kerosene due to the catalytic action of passing chlorine over the metals magnesium gave 0.3 per cent, aluminium 15.9

per cent, and for the non-metals silicon 0.6 per cent, sulphur 0.7 per cent, phosphorus 1.7 per cent, and selenium 5.3 per cent on the basis of the oil used.

5. The difference in the per cent of conversion to gasoline between the use of hydrogen chloride and chlorine upon magnesium and aluminium is marked. Hydrogen chloride upon aluminium gave 37.3 per cent yield, whereas chlorine, acting upon same metal, gave 15.9 per cent.

Blast Furnace Irregularities and Their Treatment

BY J. E. JOHNSON, JR.

Regularity the First Requirement of Successful Operation

The keynote of successful operation of the blast furnace is regularity. I have tried in preceding chapters to make a picture of the delicate equilibrium which must be maintained between enormous forces, and I have tried to show that variations of only 1 or 2 per cent were enough to affect seriously the results of the operation, while a change of 5 or 6 per cent might be fatal.

The regularity required is of many kinds. First: uniformity of the stock charged; second: uniformity of its distribution into the furnace; third: uniformity of the blast in temperature and humidity; fourth: uniformity in the distribution of the blast in the furnace; fifth: uniformity in the quantity of blast blown per unit of time; sixth: uniformity in the kind of material to be produced. It may take days or even weeks to establish the absolute equilibrium which gives best results in cost, quality of product and output, and this cannot be secured at all except by regularity in all these factors. A temporary variation in only one of them may bring about conditions which will necessitate days of careful watching and adjusting in order to restore the furnace to the desired condition.

Undoubtedly the most important kind of regularity is that which leads to regular and uniform driving of the furnace, that is, to steady and continuous working. Many furnacemen have in times gone by followed the practice of tuning everything up for weeks and then making a sudden spurt in which gigantic outputs were secured generally, assisted by melting up a scrap accumulation of weeks, trusting that this spectacular performance would divert attention from the mediocre work which preceded, and the rotten conditions which followed the conclusion of such a spurt. But it is now well recognized not only by furnacemen but by managers that it is the long steady pull which counts rather than the spurt, and spurring for a record has very seriously declined in favor of the great benefit of the business.

The Furnace Plant Cannot Run Except When All Its Parts Run

The furnace plant is different from all other large plants in one particular. It has no reserves, no storage capacity, so to speak, at any point on the line so as to permit one part to run and store up a supply of its particular function that lasts while the function itself is suspended for repairs or the like. For instance, in the steel plant, not counting the mixer, since that may be classed with the bins of the furnace system, there is a storage interval of at least a few minutes before tapping, then after tapping the steel is poured into ingots and these are many hours in making the round trip,

¹⁰Landolt & Jahn, Z. Phys. Chem., 10, 363, 1892.

¹¹Eglioff and Twomey, MET. AND CHEM. ENG., 14, 247, 1916.

¹²Work now going on in this laboratory for the isolation of unsaturated and saturated compounds from the cracking of petroleum, shows that amylene and pentane are readily formed from high molecular weight paraffin hydrocarbons.

¹³Chem. Zentr., 53, 12, 353, 1881.

though the actual time of pouring and stripping is but a small fraction of this. This means that there is a considerable volume in the ingot molds. Then there is storage again after the ingots are removed from the molds and put into the soaking pit, and so on, there being some storage capacity, be it great or small, in almost every part of the process, but in the blast furnace this condition does not exist. It is necessary that *all* the parts of the furnace operation be co-ordinated with one another in the closest possible way.

If the blowing engine stops the furnace stops instantly, and more than that, if the blowing engine stops without the furnace being flushed or cast the cinder is likely to fill the tuyeres which causes an enormous amount of labor for its removal and a delay of many hours. If the filling apparatus becomes deranged and the furnace can no longer be filled, it may be run for a short time, but if for more than an hour or two, even though filling be resumed at the end of that time, the stock filled immediately after the intermission is deprived of a considerable proportion of the time and exposure to the gas which it should receive, and reaches the hearth in a raw condition, deranging the work of the furnace. Consequently, if the filling arrangements become deranged to any considerable extent the furnace must be cast and the blast taken off. If the stop is to be a long one the tuyeres must be plugged up for reasons already pointed out. If, on the other hand, the arrangements for disposing of the iron or the slag, particularly the former, become deranged, almost the worst condition of all arises, especially if the derangement is so great that the iron already in the furnace cannot be tapped out.

If it can be foreseen therefore that the iron cannot be taken care of as made, the furnace may be cast and shut down as before, but in none of these conditions is there any considerable margin of time, and it is true of the blast furnace as it is of no other industrial apparatus within my knowledge, that all the parts must function simultaneously, and stoppage of one stops all.

The Nature of the Irregularities

The variety of mishaps which can cause shutdowns of various kinds is almost infinite. They may be divided into two broad classes. First: those in which the derangement is of the furnace itself; second: those in which it is that of some of its secondary functions. That is to say, the furnace may be running beautifully, but a breakdown of the filling system shuts it down, or as was the most frequent cause of all within a few years, a breakdown of the blowing power stops it. These and all similar failures, external to the furnace itself, are more or less mechanical, and while plenty of them are serious enough and require enormous labor for their repair and cause great loss not only in the actual cost of the repairs themselves, but in the loss of time on the whole plant, they do not affect the furnace itself except as the result of a long stoppage, as has been described under that heading.

On account of the variety that is possible in such failures and the fact that the making of repairs in such cases does not differ from that of making similar mechanical repairs in other industries, I shall not attempt to describe them here.

Derangement of the Furnace Proper

With the other class of accidents or derangements those which affect the functioning of the furnace itself the conditions are very different. They are unlike anything else in industry, and the knowledge of how to handle them and restore the plant to operation would not be given by the most intimate acquaintance with all the other industries in the world. There are several degrees and varieties of these derangements, both

as to cause and as to effect produced. As to the causes the most frequent are, 1, heavy slipping; 2, internal explosions; 3, the breaking of a scaffold and the descent of the material which formed it into the hearth; 4, the cutting or bursting of a water-cooling member, such as a tuyere, cooler or cooling-plate; 5, breakouts; 6, a mistake in filling such as charging ore without sufficient fuel to take care of it.

The results of these various causes are, of course, very different when they are not serious, but strange as it may appear, when the results are serious they are practically always the same in a general way, though they vary infinitely in details. They are the chilling or partial chilling of the hearth of the furnace, so that the material can no longer be easily withdrawn in the molten condition; this causes the rest of the various conditions which follow. The reason for this is that a serious derangement from any of these causes brings about either the descent into the hearth of a large amount of insufficiently prepared material, or else a long stoppage of the furnace, which, occurring suddenly and without warning, means that no extra coke can be put into the hearth to meet it so that progressive freezing up occurs, its severity being proportional to the delay.

SLIPS

In the article on Mechanical Principles the actions which lead to sticking have been quoted from my paper, "Notes on the Physical Action of the Blast Furnace," and while the mechanism therein described may be subject to infinite variations of detail in that various circumstances affect and cause such sticking, the universal first remedy is the slacking of the blast so that reduced pressure below may cause the weight of the suspended material to bring it down. Slipping when almost continuous and not violent is spoken of as "sliding," and when even less violent, but still causing the excessive discharge of flue dust, as "dusting." I give below a further quotation from the same paper which covers both "kicking" or ordinary "slipping," and also those more violent accidents really deserving the name of explosions, which both in this country and others have, in some instances—fortunately only a few—resulted in bursting the furnace shell, or sometimes the bosh structure, with the violent ejection of the contents of the furnace.

EXPLOSIONS

"There come, however, occasionally, occurrences of this general type, but of so much greater violence and destructive effect than mere "slips" that they seem to require a further explanation.

This seems to be furnished by the fact that the conditions I have described may occur at any point in the furnace, and that the deeper they are the greater is the air-pressure, and also the weight of the ammunition in the air-gun thus formed; hence the greater the execution.

But if this occurrence take place so low in the furnace that the cavity formed reaches finally down to the tuyeres, a further condition arises, in which the cavity is filled not with gas but with air; and when the break in the obstruction comes, the incandescent carbon dust always present in the lower part of the furnace from the splitting up of the CO is precipitated (along with the other materials) into an atmosphere of compressed and heated air, giving precisely the conditions requisite to the production of an explosion of great violence, in which case the air-gun becomes a powder-gun, and is not infrequently burst by the charge. This accounts completely for the observed phenomena of these more violent occurrences.

As already explained, the "kicking" due to slips is

more violent and prolonged in proportion as the obstruction is deeper in the furnace. But there is still another reason for the shades of increasing violence, which make it almost impossible to tell where slips end and explosions begin; that is the varying quantity of unburnt air in the cavity above the tuyeres and the degree of its mixture with other gases. This is due to the gradual decrease in the depth of the layer of coke above the tuyeres. When this is no longer sufficient to burn all the oxygen to CO, CO₂ begins to appear, and when there is not enough to burn it all to this, free oxygen begins to appear, and its percentage thereafter steadily increases. It is evident that the precise point in this series of changes at which the slip takes place will influence profoundly the character of an explosion, and even the possibility of its occurrence."

One case is on record in Germany in which nothing but a stump of the furnace was left after the explosion. Another occurred soon after the introduction of Mesabi ores in the Shenango Valley, in which the furnace shell was completely wrecked. More recently at a furnace in the Pittsburgh district the bosh was torn wide open without a second's warning. The great steel bands around it, 10 in. by 1 1/4 in. and only about 1 ft. apart, were ripped in two as if they had been threads cut with a razor and almost the entire contents of the furnace were discharged through the great opening made, almost half the bosh wall being blown away.

These terrible accidents accompanied as they so often are by serious loss of life, each occur under different circumstances and with different results. Fortunately, they are too few in number to be classified broadly and accurately, but in general no two agree very closely. Many explanations have been given for each and every one, and a greater number of theoretical causes have been assigned for the production of the explosion which brings about such terrible results, but after careful consideration of them all I have been unable to find any cause as inherently probable, or with as few practical or theoretical objections as that advanced in the quotation just given.

Certainly if the fuel bed above the tuyeres burns down much below the top of the bosh while the balance of the stock stays suspended above it, we shall have a great cavity filled with an atmosphere containing free oxygen at a temperature well above 2500 deg. and under a pressure perhaps of 20 to 30 lb. If now we precipitate into this a great mass containing a large proportion of incandescent carbon in the condition of impalpable powder, what can we possibly have except a dust explosion under the conditions far more favorable to violence than those which have enabled such explosions to wreck coal mines, flour mills and other industrial operations almost without number?

Many other reactions have been proposed as the cause of these explosions, but not a single one that I have ever heard advanced will stand the test of representing the conditions truly and being at the same time chemically correct.

SCAFFOLDS

These can scarcely be treated separately from slips, since scaffolds are one of the most active causes promoting slips. Projecting out from the wall of the furnace they offer support to the charge column and in conjunction with the pressure of the blast from below they support its weight so completely that it ceases to descend until the blast is checked or some keystone of the crude arch formed dissolves away and the mass descends, causing a slip.

Scaffolds are of many and various kinds. It is probable that a large volume could be written concerning this subject alone had anyone the patience to collect all

the data available. In general, however, scaffolds confine themselves to the region from the top of the pasty zone downward. Some furnaces which work "tight" are said to have dust scaffolds, but I have always preferred to believe that this was a condition of tightness at a certain zone due to the continuous redeposition in that zone of carbon dissolved at a lower level, according to an action earlier described.

Leaving these we have only to deal with scaffolds formed of molten or semi-molten material. They may be a foot or two thick radially or they may form a complete floor across the furnace. Of the latter I have heard several times, but fortunately I have never seen myself. The blast furnace is understood so much better now that those occasions are becoming very rare if they have not gone forever. But scaffolds from a foot to several feet in thickness are still not uncommon; in plan they may extend from a bare lump on the side of the furnace to a complete ring all around it, almost as regular as if it had been built on purpose.

In regard to the latter I can speak with certainty for I have had the unusual experience of seeing such a scaffold in a "live" furnace, just after it had caused its victim to undergo one of the explosions which I have just described, and to throw out its entire contents to a point well below the scaffold. It was an experience that I shall never forget. I was at the time on the upper platform of a steeple-type blowing engine, which was running along quietly enough when suddenly something happened which I have never been able to compare to anything except the blow which an unsuspecting man might receive from a blackjack; he would be knocked to his knees for a moment and then get up and run away. The blowing engine seemed to receive just such a shock, and after a few seconds went on much more easily than before the shock had occurred.

A prolonged roar and a lively fusilade on the engine-house roof announced that something out of the common had happened. On going out to investigate I found that a real explosion had taken place and the furnace top was evidently completely deranged. The furnace was cast and stopped as soon as possible, and when we were able to reach the top we found the bell resting securely in the hopper on top of the lip ring instead of beneath it.

Investigation showed that it had been driven upwards with such force as to break the lip ring in two and force it up in the hopper until the bell could pass through it, then the lip ring dropped back to its seat with the bell on top of it. The enormous bell beam built up of heavy plates and angles was bent at a sharp angle, though the forces required to do this must have reached hundreds of tons. Other things were about in a similar condition.

After the top was cleaned off and cooled down enough to work two of us finally ventured to lean over far enough to look down inside; as several hours had passed all was then quiet and we could see a dull red "ring" scaffold running all around the furnace at a height that seemed up somewhere above the top of the bosh, and seemed to extend out some 3 ft. all around. As the furnace was 21 ft. in diameter this would have left a 15-ft. hole through the center. It may even be that the scaffold was greater and the hole smaller than this.

I take this case to be almost ideal proof of the accuracy of the theory of explosions described in the last section. The whole charge column taking advantage of some accidental variation, high pressure or the like, evidently came to rest on the top of the scaffold, and being at the top of the pasty zone it held there while the lower portion settled as the coke burned away. In a comparatively short time, two or three hours at the

most, the surface of the lower portion descended well below the top of the bosh and the height of the fuel bed was no longer sufficient to prevent the presence of some free oxygen in the space above it. Finally something happened to precipitate the suspended mass above through the central hole in the scaffold and the explosion, which I have so inadequately described, instantly followed.

It is easy to see that a ring scaffold of this kind is the most dangerous that we can have, in spite of its symmetry, because it furnishes such ideal support for the charge column and tends to stop the descent of the latter so completely. A scaffold on one side only tends to check the material on that side and to force the fines over to the far side of the furnace, the lumps running back under it. This produces a very uneven descent of the charge into the hearth and a highly improper distribution of the gas current through the descending charge, but this, though bad enough, is obviously not so serious as the complete suspension of the charge with results like those above described.

THE REMOVAL OF SCAFFOLDS

This is a subject concerning which we know far less than we should. Many furnaces which once become scaffolded never work satisfactorily again during that blast, while again others may get rid of the trouble completely and do as good work after as before. In general, there are three methods to be pursued. First: to restore conditions as nearly to normal as possible, running with a comparatively light burden and hoping to melt or wear the scaffold away whatever its position. Second: by careful watching of the working of the different tuyeres to try and locate the position of the scaffold and then try so to direct the filling as to overcome as far as possible its bad effects, or by directing the action of the furnace violently against it to wear it away. Third: by deliberately sacrificing the work of the furnace for a day or two, putting in a light burden with a considerable excess of whatever material will produce the most fusible slag, generally silica with a coke furnace, although silica and fluorspar would be better, lime and fluorspar for a charcoal furnace and by extra heat and dissolving action scour it bodily off.

In the case of a coke furnace I have known the ore burden to be almost entirely replaced by a great quantity of sand. Coke-furnace accretions always contain a considerable quantity of lime, as already pointed out, so when this great quantity of unfluxed silica reaches these accretions in the presence of a great excess of fuel to produce all the heat necessary, it at once tries to satisfy itself with bases by dissolving away the accretion. I have never tried this drastic remedy myself.

On the other hand, charcoal furnaces, especially when they are run on very lean slags, build up on the walls with that fusible but tough and stringy material. These slags are decidedly on the silica side of the most fusible slag, and by lightening the burden and adding an excess of lime for a day or two they may generally be scoured off completely. This I have done more than once.

THE DESCENT OF UNREDUCED MATERIAL INTO THE HEARTH

Obviously every time the furnace hangs and then slips we have a condition which deprives a part of the material of some of the time which it should have had for preparation in its descent through the furnace. But in the upper part of the shaft where we have the greatest surplus of heat and in general a surplus of reducing power, such a slip is not of much consequence unless it represents hanging for the space of an hour or more.

But as we go further down into the furnace the mar-

gins of heat and of reducing power are lower and lower, and the time in which to make up for treatment lost is smaller and smaller, so slips become not only more violent because of the higher pressure from which the furnace is relieved, but more serious, and their effect on the action in the hearth may be disastrous, especially if the shaking up which occurs at that time permits the ore to run ahead of the coke and come down into the hearth before the coke which should accompany it.

Obviously in this case we have material very inadequately prepared in the first place, and yet have no coke appropriated, so to say, to the purpose of finishing the smelting action of the furnace upon it, let alone supplying any deficiencies in reduction. The same is true in the case of the breaking off of a scaffold and the descent of its material into the hearth.

The Chilling of the Furnace

In all cases of chilling of the furnace we have an action which is serious in proportion to the amount of incompletely prepared material involved.

If this be small it may be taken up by that latent reserve of heat which the furnace seems to possess, without producing a very serious result. But a very moderate amount of material so precipitated into the hearth brings about a complete derangement, first: the incomplete reduction of the iron which passes into the cinder, turning it as black as tar; second: the cooling of the hearth with its resulting insufficient desulphurization and the ruin of whatever iron may be produced in consequence; third: insufficient heating of the slag and iron to permit their discharge from the furnace through the normal apertures in the proper way. Finally, the chilling of a heavy scull of iron, frequently low in carbon, around the whole interior of the hearth and the lower part of the bosh, making the task of drilling in to discharge either iron or cinder very difficult. This is quickly followed by the freezing of the iron in the lower part of the hearth so completely that it will not run no matter how far we may drill into the tapping hole, which is then "lost." This in turn is followed by the freezing up of the iron and cinder around the tuyeres until perhaps only one or two are left sufficiently open for a little blast to pass through. Meantime it having been impossible to withdraw anything from the furnace, and some blast going in continually, combustion continues and more slag continues to be formed, and in the greater quantity because a great percentage of all the iron also passes into it.

We have now a furnace containing many tons of molten material to a height perhaps several feet above the tuyeres, the bottom of the hearth solid with frozen iron in its toughest condition, and a scull of iron or steel all around the upper part of the hearth and the lower part of the bosh, which prevents our making any opening at the cinder notch for the withdrawal of the cinder which has accumulated. We know that we cannot go on indefinitely, that, for instance, the liquid pressure of the thin, violently active, scouring cinder inside the furnace increases the liability of its breaking out at some point, and the certainty that when it does so the running stream will cut almost anything that comes into its path, will run all over the ground and make access to the aperture almost impossible, and that if the engine fails this huge mass of slag will seek its own level in the penstocks and bustle pipe, and that if on top of present misery a slip occurs it will force the slag into the blow pipes and penstocks, even against the blast pressure.

When this condition is reached the furnace is technically said to be "in a mess." Any furnaceman who has ever passed through the experience will admit that

the term is literally as well as technically correct. If he be consulted at the time he will probably express an unfavorable opinion of a man with so little judgment as to enter a business capable of producing such horrible conditions.

These are also the conditions in a general way which result from other causes, a long stop without warning, a mistake in the filling by charging too little coke, a bad breakout followed by water running from the ditch through the hole made by the breakout into the hearth and standing there for hours because the breakout had effectually dammed the ditch, which I once experienced, and various others.

The question is what course must be pursued to restore those normal conditions which bring profit to the owner and comparative peace of mind to the operator and the crew.

A little consideration shows that no matter what the ultimate cause may have been, the immediate cause of the difficulty is the absence of sufficient heat to bring the materials in the hearth to the temperature at which they will run out, and if my description of the terrors of such a condition were adequate (which it is not), it would perhaps explain my tiresome insistence in earlier chapters on the free-running point as the critical temperature of the furnace and on the vital necessity of enough heat in the hearth to bring about this temperature.

The remedy is then to introduce more heat into the hearth. But our chief method of doing this is to introduce more fuel and we can in general only introduce this at the top of the furnace, and in order to permit its descent into the hearth all the charge in the furnace at the beginning of the trouble must be worked out. This requires from eight to twenty hours, depending on the rate of driving, even in normal operation, when all the molten material can be removed as formed, in a truly liquid condition; but when the furnace is in a "mess" the possibility of such regular removal has vanished, in fact, we might define a mess as any condition which made the free and regular removal of the molten material impossible.

We must then find means to carry on such removal as best we may until the blank of coke charged to give relief can reach the tuyeres, and this period is prolonged just about in proportion to the difficulty of slag and iron removal. For this reason the wise furnaceman when he sees signs of impending trouble, charges a good blank of coke knowing that even if it does not reach the hearth in time to avert serious trouble it will shorten by so much the weary interval of difficult and irregular flushing and casting.

If the mess arises through a breakout or mechanical breakdown, which causes a long and utterly unexpected stop, he charges the blank the first thing on starting up, and if the difficulty threatens to be a serious one he lightens the burden to a material extent so as to have a reserve of heat to overcome the irregular conditions which will probably persist long after the blank is gone and the furnace once more in operation.

Steps to Be Taken in the Early Stages of Chilling

The important question is, "What methods are to be used to remove the slag and iron after the regular methods fail?"

As the furnace loses its normal supply of hearth heat, the portion farthest from the tuyeres naturally feels the loss first and therefore the iron in the bottom of the hearth, where the regular tapping hole is, freezes so that no iron can be drawn from it; sometimes the drill simply encounters a mass of red hot tough pasty iron which it cannot penetrate, more rarely it goes half

across the furnace underneath the iron in a mass of brick, slag and heterogeneous material which can be drilled but which will neither run nor allow the iron to run.

In such a case the molten iron lies higher up and ordinarily other holes are drilled at successively higher levels until liquid iron is reached or it is found impossible to reach it.

In some rare cases a dry hole under the bottom of the scull in the hearth may be shot with dynamite and the scull broken through up into live iron above, which will then flow out. It must be remembered that the hole is between red and white hot and the radiation from it is sufficient to set off the dynamite in a few seconds so this operation is not to be regarded as a safe and harmless pastime. On the only occasion when I used this expedient the hole was drilled well back to the center of the furnace, so there was no danger of damage to the hearth jacket as there would be with a shallow hole; the dynamite was wrapped in rags soaked in thick grout and laid on a little wooden trough or boat so as to keep it from contact with the bottom of the hole; the fuse was cut to burn only a few seconds, it was lit after the charge was placed in the trough and the latter was quickly pushed down to the end of the hole with a long rod and all hands retired to a short distance without unnecessary delay, and waited until the explosion came. This was followed by a small river of iron and our troubles were over for that time.

Generally, however, no hole can be drilled at all at the bottom and it becomes necessary to go higher and higher to reach the iron. When the top of the iron notch opening through the hearth jacket is reached and still the scull around the hearth cannot be penetrated the tapping hole is "lost" and it is then necessary to go to the cinder notch.

Casting Through the Cinder Notch

The construction of the latter is excellently designed for the purpose for which it is normally used, the quick, easy and safe removal of the cinder. But while water-cooled bronze will withstand molten cinder of almost any temperature, it will not withstand molten iron at all, or, at least, it is likely to fail in a few seconds under a flow of iron, especially the raw, scouring and extremely corrosive material which is produced at such times.

The failure of the water-cooled bronze parts is certain to result in a violent explosion, and therefore before casting through the cinder notch the bronze cinder cooler must be removed. The monkey will probably have been "pulled" already on account of stiff, sluggish slag. If there be an outside iron cinder cooler it must take its chances because it cannot be "pulled." The danger of having this cut is much smaller, and bad explosions are not so likely to follow if it is, and whatever risk there may be is further reduced by making up a bed of sand or clay in the bottom of it. An emergency runner of sand is built from the cinder notch back into the iron trough if possible or else to the iron ladles or the pig beds.

One disagreeable consequence of casting through the cinder notch is that the iron cinder cooler, if there be one, or if not the brick surrounding the hole, are cut and roughened by the scouring mixture of iron and cinder, which is always to be expected under such conditions, and lumps of iron or cinder are left burnt onto the brick or the iron cooler as the case may be. The temporary bottom of sand brick or clay used to pave the bottom of the opening helps to prevent this, but the lining is likely to be knocked off, particularly on the side. These lumps are very difficult to remove when they do

become burnt on and unless they are removed the bronze cooler cannot be put back to its proper place. They are, therefore, very objectionable.

In order to protect the hole completely, I have used very successfully the expedient of inserting a piece of common wrought-steel pipe about the size of the inside of the bronze cooler and packing around the outside of it with clay. The pipe may burn up during the first cast through it, but usually lasts several. When burnt up it can readily be replaced, and when normal conditions are restored it can be pulled out and the clay packing of the pipe removed without difficulty, leaving the brickwork or the iron cooler, as the case may be, in perfect condition. This is a small matter, but it may save hours of work and injurious delay in getting back to normal operations.

When all the necessary arrangements have been made the next thing is to drill through the cinder notch if possible. When this can be done the furnace can be kept in fairly steady operation and the life-saving blank worked down to the tuyeres without undue delay, and the trouble is then likely to be pretty well over.

Opening a Chilled Hearth

But if the scull is too hard to drill and too rough to drive—then the real trouble begins. To force an opening we have now available four means, dynamite, the kerosene blowpipe, the electric arc and the oxygen burner.

DYNAMITE

If the hole has been drilled back well into the scull so that the latter shows red hot, then the hole can some-

times be shot open with dynamite. The charge should be made up in a cartridge made of a piece of pipe 2 in. or 3 in. in diameter and mounted on the end of a long piece of small pipe for a handle so that it can be set off instantly when the cartridge has been placed in the hole. This latter is not a particularly pleasant job because the dynamite may be exploded prematurely by the heat of the hole. There is, of course, no time for tamping and much of the force of the shot is lost, but by following up with larger cartridges as the hole swells the scull can sometimes be torn open.

I once saved by this means a furnace which had lost not only the tapping hole and the cinder notch, but also all the tuyeres but two. We shot open a "dead" tuyere, into which we had drilled as far as we could in trying to flush through that, its level was too high to give good drainage from the other tuyeres, but opening it removed a huge mass of molten and pasty material which had been held up in the bosh by the blast pressure. This gave us time to take further steps and really saved the day.

The closing of this hole was no joke; the drainage afforded was incomplete because only on a level with the tuyeres, so if the blast were taken clear off the cinder came back into our only two remaining tuyeres. Of course, with the blast on even very little the big hole which the destruction of the tuyere had left, discharged flame and shot cinder about like a small bessemer converter. We finally checked the blast with the snort valve to the point where the cinder was barely kept out of the tuyeres and reduced the discharge of flame and shot cinder to the point where one of our

keepers volunteered to stop the hole, which he did with clay balls and a stopping hook. The job only took two or three minutes, but his overalls were practically burnt off him by cinder shot when he finished; it was one of the pluckiest acts I ever saw. Such details will perhaps help to give some idea of the conditions likely to arise during a mess.

The conditions under which dynamite can be used successfully are rare and its use is always highly undesirable because of dangers to which its use exposes the plant as well as the crew, and in consequence it is not often used.

THE KEROSENE BURNER

Probably the first means developed for meeting these conditions was the kerosene blow-pipe. Its use gives such very different results, according to its control, that it has been utterly condemned by some good furnacemen, while it was regarded as a life saver by others, before better means took its place.

Some experience with these blow-pipes and some of the principles on which their successful use depends were described in the *American Machinist* ten or twelve years ago and a portion of the article is quoted here.

The oil burners shown in Figs. 1, 2, 3 and 4 were made in great haste and in almost total ignorance of the details of their construction, as far as experience was concerned. A piece of $\frac{1}{4}$ -in. pipe was welded shut on one end and a $1/16$ -in. hole drilled through this end. On the other end of this pipe a long thread was cut, which was screwed into a bushing, filling the rear end of a $\frac{3}{4}$ -in. T. At the side of the $\frac{3}{4}$ -in. T the air entered through a nipple and hose. The $\frac{3}{4}$ -in. pipe in the front end of the T in the first burner made was about the same length as the $\frac{1}{4}$ -in. pipe inside (about 4 ft. long), and on its end was screwed a reducer, into the end of which a $\frac{1}{2}$ -in. nipple, about 4 in. long, was screwed.

This burner was very successful, though used under lighter air pressures than those we subsequently obtained, but having been the first one made, it was, perhaps, natural to think that subsequent ones should be better; so desiring another, the $\frac{3}{4}$ -in. pipe was drawn down by a smith to a conical end or jet much better looking than the reducer and $\frac{1}{2}$ -in. nipple, as shown in Fig. 2. But after full and fair trial, it was found impossible to get the concentration of heat in one place with this that was obtained with the other, for the reason that under the heavy pressure of air the velocity of efflux was so great that combustion was not complete until a point was reached something like $1\frac{1}{2}$ ft. beyond the end of the burner. With the conical nozzle the jet action had ceased, and the lines of flow of the flame had ceased to be convergent and had become divergent within less than a foot; consequently, the flame was without any accurate center, and was quite rapidly divergent at the point where combustion was complete and where the greatest heat should have been if it had been properly concentrated, all as shown by Fig. 3.

The $\frac{1}{2}$ -in. nozzle by permitting the flow to be approximately parallel, enabled the combustion to be complete within a small area at whatever distance from the burner might be necessary within reasonable limits, and, therefore, focused the activity of the flame much better than the convergent nozzle. This, at least, seemed to be the theory, and these certainly were the facts, as was clearly proven by cutting off the convergent nozzle and substituting for it the reducer and $\frac{1}{2}$ -in. nipple.

Another improvement, shown in Fig. 4, was attempted, with the object of heating the oil further by the action of the $\frac{3}{4}$ -in. pipe upon it before it reached the point of discharge. It should have been stated above that the oil was delivered by pipe and hose connection

from a barrel placed at the top of the furnace, some 70 ft. above, so that there was a very good head to drive it through the $1/16$ -in. hole, and a sufficient quantity emerged to make a very large flame. The quantity was regulated by a $\frac{1}{4}$ -in. globe valve on the projecting end of the $\frac{1}{4}$ -in. pipe, at whose inner end was the $1/16$ -in. orifice. The operator regulated the action of the blow-pipe by opening or closing this valve minute amounts to suit conditions, and also fed the nozzle or drew it back so as to keep the hottest part of the flame in the point where the melting was desired to take place. The improvement, which was attempted, consisted in cutting off the $\frac{1}{4}$ -in. pipe which carried the oil about 1 ft., so that the oil had to traverse about a foot of space through the $\frac{3}{4}$ -in. pipe before reaching the $\frac{1}{2}$ -in. nozzle, the idea being that it would in this way be preheated more than by simply passing through the $\frac{1}{4}$ -in. pipe for the same distance.

The attempt to operate this burner was most exasperating and unsatisfactory. If the valve were regulated to bring the flame to the right condition, it would sustain itself for a brief instant, go out, and be followed by a surplus of oil which re-ignited against the hot surface and made a detonating mixture with the air with which it had become mixed during the instant of extinction, so that virtually the action of the burner was no more than a series of sharp explosions at intervals of about a second, with, of course, no useful heating effect.

No regulating of the valve sufficed to cure this most objectionable condition, but finally close observation showed that coincidentally with the flashes of re-ignition there came a few drops of oil in liquid form, not spray, from the end of the $\frac{1}{2}$ -in. nipple. It was these which supplied the excess of combustible and made the smoky flame accompanying the explosions (which, of course, were perfectly harmless in their nature).

When this was seen the secret was out. The oil was not driven with sufficient force to throw it entirely into spray at the base of the $\frac{1}{2}$ -in. nozzle, but some of it ran down and along the bottom of the $\frac{3}{4}$ -in. pipe, whence it was picked up and carried in waves by the action so familiar to all in such cases, with the result that there was first an excess and then a deficiency of fuel for the air, the supply of which was constant.

A longer $\frac{1}{4}$ -in. oil pipe was at once procured, which delivered the oil just at the base of the $\frac{1}{2}$ -in. nozzle, where the high velocity of the air consequent on the reduction of area caught it and threw it into a perfect spray, so that the action was complete and continuous. This perhaps may be a useful experience for those who have to do with oil burners as a regular occupation.

Another point of much interest in connection with these oil burners came to light during the brief experience, of which mention has been made. This was that the burner did better the deeper the hole in which it was working. The reason was not very far to seek. When the hole was quite deep, say 2 ft., and of comparatively small diameter, the flame which, had it been unobstructed, would have gone perhaps 7 or 8 ft. beyond the end of the burner, was compelled, by striking the object of its attack, to return on its course and come back over the burner itself. The result would have been that the burner would have been heated to a white heat in a very few minutes had it been a piece of "dead" pipe of the same size in the same flame, but as a matter of fact the burners never showed the least inclination to get even red hot, being cooled by the rapid current of air through them. The other phase of this fact is that the air must have been heated before leaving the burner to a very considerable degree. One could even imagine that it may have been 500 or 600 deg. Fahr., though

naturally no effort was made to determine the amount at that time.

Just what the flame temperature in such a case is I do not know. Theoretically, it would probably be 3500 deg., or perhaps more, but actually would not likely be above 3000 deg. If, now, the fusion point of the substance to be melted were 2500 deg., then an increase of 500 deg. in the temperature of the air, giving an increased flame temperature of perhaps 400 deg., would make the latter 3400 deg. instead of 3000 deg.; and while this is not a very great difference absolutely or relatively, based on the total temperature, when compared with the fusion temperature (assumed to be 2500 deg.), it is seen to be almost twice as great a difference, implying twice as much heat available for melting operations, as well as nearly twice the "thermal head" for causing the heat to flow from the flame to the object being melted. Moreover, it is almost certain that the oil inside of the $\frac{1}{4}$ -in. pipe was somewhat preheated also, and, therefore, its vaporization at its exit from this pipe was much quicker and more complete.

Much larger oil burners are sometimes used, in some cases a 2-in. pipe for air and a $\frac{1}{2}$ -in. pipe for oil, and in some cases no nozzle is used because it melts away in the intense heat developed, the pipes simply discharging through their open ends.

The necessity of having the focus of the jet coincide with the zone of complete combustion has been shown by all my observations, and it is this fact which makes it so difficult to secure the best results with these burners, because we have four variables to regulate; the distance of the nozzle from the surface to be fused, the velocity of the jet depending on the pressure of the air at the nozzle, and the quantity of air depending on the size of the pipe as well as the pressure, and the quantity of oil.

The fact that the volume of air and its velocity which should vary independently, must actually vary simultaneously, is perhaps one of the greatest difficulties. Sometimes it seems impossible for one man to obtain a satisfactory adjustment of all these variables when another will have no difficulty. On one occasion my assistant, the master mechanic, and I all failed to do any good with one of these burners, but the colored pipe fitter came along and did good work with it.

One vital fact to remember is that the best fuel for generating heat to melt iron is the iron itself, not only because of the heat it develops, but because the iron oxide slag formed as a result melts at a much lower temperature than iron. For this reason no burner ever works successfully except with an oxidizing flame. A reducing flame makes a pretty sight and a lot of light, but does no good whatever, whereas an oxidizing flame, making a hideous roar and showing only a short blue flame, will really cut. After the point of attack is heated to the proper temperature the supply of oil should be reduced to the minimum so as to leave as much oxygen as possible free to burn the iron.

Later and far better methods of burning open-chilled top cinder notches and the like have laid the kerosene burner on the shelf for most conditions, but for isolated plants caught in a mess without the modern apparatus they are not to be despised.

THE ELECTRIC ARC

Heat developed by electricity differs in one important respect from heat developed by combustion. Its temperature of application is virtually unlimited, from the industrial point of view at least, while we have seen the rapid increase in limitation to combustion heat, which rise of temperature causes. Electric heat has then an increasing advantage as the temperature of application

rises and this is, of course, greater in fields where the actual amount of heat required is small.

These conditions are exactly those of melting out a frozen cinder notch or tapping hole.

Nearly all blast furnace plants of importance have an electric plant of some size and very early in the present century it was found that the electric arc could be used in such cases with tremendous advantage, and the practice rapidly spread.

The chief consideration next to having sufficient energy available is that the voltage shall be low. In the description of the removal of the salamander in a previous article, the reasons for this are given and need not be repeated here. The voltage preferred for this service is about 50 and at least 1000 amperes should be at hand. Twice as much is better. This gives a short controllable arc and the melting can be done where it is needed.

Alternating current has the great advantage for this service that the approximate voltage needed can be obtained directly from suitable transformer, whereas direct current must be choked down in voltage through a water rheostat or some equivalent. This is not only wasteful of power, but the apparatus is clumsy and the control not easy. At one large plant a transformer of suitable size and design was located permanently at each furnace so that it was only necessary to place the carbon and turn on the current. A hole can be burnt in a short time into any place where there is enough conductivity to carry the current.

THE OXYGEN BURNER

Modern progress has brought into common use the oxyhydrogen and oxyacetylene blow pipe and developed comparatively cheap methods of producing the gases so that the use of these means for cutting iron and steel as well as that of oxyacetylene for welding is growing at an exceedingly rapid rate. Carloads of oxygen cylinders are now more common than single ones were not long ago. The application of this apparatus to frozen cinder notches, etc., was obvious, and it has now come commonly to be preferred to the arc, although the latter continues to be used.

The preferred practice is to use the blow pipe only to bring the surface to be burned up to the temperature at which it will burn in pure oxygen and then direct a stream of the latter against it under heavy pressure. The reflex velocity of the jet keeps the hole clear of the burnt iron formed and rapid action is maintained.

The results which can be obtained in this way are little short of marvelous, instead of being a matter of hours to burn through a few inches of iron as is the case with the oil burner, it is a matter of a very few minutes. In one case of which I knew, a badly frozen tapping hole was burned through and the iron running in about 6 minutes from the time the oxygen jet was turned on. With the great increase in the ease of obtaining oxygen quickly and cheaply, this process seems likely to supersede all the others. It and the electric burner together have done much to remove the terrors which a chilled furnace formerly held for the unfortunate furnaceman.

ADDING ADDITIONAL FUEL IN THE HEARTH

In the most extreme cases of chilled furnaces the material in the hearth is so chilled that the blast has but little effect, in fact, can practically not penetrate the frozen material enough to generate any heat or form any slag. In such cases the materials in the hearth are dry rather than pasty, and can be removed through the tuyeres and cinder notch by pulling out solid lumps of coke, ore and limestone.

In such cases the preferred procedure is to dig a considerable hole into the cinder notch and into the tuyere nearest to it, fill up this space with fresh lumps of coke put in from the outside, then put back the blow pipe into the tuyere. If necessary, kindling or a piece of waste is used to ignite the coke as in blowing in.

A small quantity of blast is then put on; this passes through the coke and burns out the cinder notch, thereby establishing good communication between these two and enlarging the cavity. The furnace is then stopped and the next tuyere is then treated in the same way, and by blowing through this communication from it also is established with the cinder notch. In this way, if need be, one tuyere after another can have re-established its communication with the others and with the cinder notch, while much heat is added by the combustion of the coke put into the tuyeres.

Personally, I have never had to fight a furnace that was so badly bungled up as this, but the process has been used by experienced furnacemen who have described it to me.

Another expedient which is well recommended by those who have used it but which I have never tried, is the use of kerosene in the tuyere itself.

A small pipe is put through the peep-hole in the elbow of the penstock and run practically to the inner end of the tuyere. This is supplied with kerosene under pressure from a tank above and the blast turned on. This converts the whole tuyere into a gigantic blow pipe and permits imparting to the furnace a great amount of heat at the point where it is most needed. In this case also, if the bosh is too completely chilled to permit of passage of gas formed an outlet must be made through the cinder notch or perhaps through another tuyere, as in the previous case.

The details of these operations necessarily vary almost infinitely according to the judgment of the operator and conditions to be met. It is therefore impossible to describe them in detail, but the general outline of the operations is as described.

A Method of Exhibiting the Velocity of Iodine Ions in Solution *

BY S. W. J. SMITH

The apparatus is represented in the diagram. The containing vessel is a U-tube with widened ends as shown. The diameter of the tube may be about 0.5 cm. or less. The cross-section of the tube should be fairly uniform. Either 25 cm. or 50 cm. is a convenient (total) length for the tube if it is desired to use it in connection with an ordinary lighting-circuit voltage of 100, or thereabouts, and to obtain a rapid estimate of the velocity of the ions. The electrodes (at A and B) are, preferably, of platinum foil. The liquids used are equally concentrated solutions, containing—e.g., either 0.2 gm. or 0.1 gm. mol. per liter of potassium chloride and potassium iodide respectively. The novelty of the experiment lies in the method of exhibiting the line of separation between the solutions. For this purpose a small quantity of mercuric chloride (corrosive sublimate) is dissolved along with the KCl. In the endeavor to main-

FIG. 1—ARRANGEMENT OF APPARATUS

tain symmetry an equal quantity of the same salt may be added to the KI.

In this case a thick yellow disc of mercuric iodide, precipitated by the action of the KI upon the $HgCl_2$ contained by the KCl, will appear at the junction between the electrolytes.

The electrodes at A and B are connected to the source of supply, that at A being made the anode. The boundary at C immediately begins to move upwards. It travels as an extremely thin horizontal disc, which can be located very accurately and projected with ease. And the disc will move at speeds of the order of 1 mm. per minute, so that its motion can be followed without difficulty by a large audience, and an approximate estimate of its velocity can be obtained in a few minutes.

A table giving the results of an experiment then follows, and it is remarked that the possibility of observing the reverse motion of the ions is due to the yellow coloration produced by chlorine ions which decompose a fraction of KI.

The solution contained 0.2 gm. mol. per liter. In an experiment made to obtain an estimate of velocity under the potential gradient of 1 volt per centimeter at a definite temperature, the distance traversed by the line of separation during the first half hour of the experiment (measured by means of a small cathetometer) was 4.13 cm. The distance traversed in the second half hour was 4.53 cm. The difference was probably due mainly to a higher mean temperature in the second half of the experiment. On this occasion an ammeter was included in the circuit. The reading rose slowly during the observations. Its mean value during the hour was 0.02 ampere. The specific resistance of the electrolytes was measured at 10 deg. C. (the temperature of the room) just before the tube was filled. The mean value was approximately 55 cm. ohms. The value of the current immediately after the circuit was completed was 0.023 ampere. The area of cross-section of the tube was about 0.31 sq. cm. Hence the initial potential gradient in the tube was approximately 4.1 volts per centimeter, and the velocity of the anions, iodine and chlorine, as determined in this way, is about 0.00059 at 25 deg. C. in cm. per sec. per volt per cm. If accurate and not rapid determinations were required much smaller potential gradients could be employed.

The author concludes by referring to the solutions used, and their conductivities and concentrations. It is also mentioned that a small quantity of $AgNO_3$ might be added to the KCl solution, and redissolving the precipitate by NH_4OH . The AgI formed during the experiment being insoluble in NH_4OH then acts as an indicator, and the progress of the ions may be watched as before. It is found, however, that this method is not so satisfactory as the one mentioned above.

Future Rubber Output.—From a statement issued by the B. F. Goodrich Co., Akron, Ohio, the prospective rubber output is as follows for years up to 1921. Past production back to 1905 is also given.

Year	Production, Tons	N. E. A. Tons	P. E. Tons
1905	187	60	60
1906	1,000	68	60
1907	1,000	68	60
1908	1,000	68	60
1909	1,000	68	60
1910	1,000	68	60
1911	1,000	68	60
1912	1,000	68	60
1913	1,000	68	60
1914	1,000	68	60
1915	1,000	68	60
1916	1,000	68	60
1917	1,000	68	60
1918	1,000	68	60
1919	1,000	68	60
1920	1,000	68	60
1921	1,000	68	60

The significant feature of this table is the greatly increased growth of cultivated rubber on plantations.

Ethyl Alcohol from Wood

The Process, Its Development and Requirements

BY F. W. KRESSMANN

Chemist in Forest Products, Forest Products Laboratory,
Madison, Wis.

The European war has caused a large number of industrial changes in this country in the last year. Many industries which several years ago were in a depressed condition are now operating at capacity and in many the capacity is being increased as rapidly as building operations and manufacturing of apparatus will permit.

The alcohol producers of the country have felt this change. The ethyl alcohol or industrial distillers had felt the prohibition movement and the wood alcohol market was barely holding its own because of the generally depressed condition of the hardwood destructive distillation industry, especially the acetate of lime end of it.

Now all this is changed, the ethyl alcohol business is enjoying an unprecedented prosperity and many old distilleries that had not operated in years are working at full capacity and several very large new distilleries have been built. In fact, the industry was contracted up to such an extent that an order for 2,000,000 gallons of 95 per cent alcohol for immediate regular delivery went begging for some time.

Because of this greatly enhanced value of alcohol for war purposes and because of the tremendous and alarming increase in the cost of gasoline, the production of ethyl (grain) alcohol from wood should receive the undivided attention of the large sawmill operators and other producers of wood waste. For this reason a brief history of the production of ethyl alcohol from wood, especially as the process has been developed in this country, along with a description of the process, plant requirement, and estimated cost of production, we believe, will be of particular interest at the present time.

For, in addition to the foregoing factors, a number of others may be mentioned that would operate in favor of wood as against grain and molasses for the production of alcohol. The war, of course, has increased the value of grains which has made itself felt in turn in the cost of ethyl alcohol from grain. Much of the molasses distilled is imported from Cuba, Porto Rico and Hawaii. The price of molasses has increased because of great increases in ocean freight rates; in Hawaii, for instance, large quantities are being burned to recover the potash in the ash, the molasses being worth over \$15 per ton for its potassium content alone.

Corn yields about 2.4 gallons of 190 proof alcohol per bushel, and although the price of corn has varied considerably,* both seasonally and annually, and especially in the last few years due to the war, the average cost of the materials used for making grain alcohol (fuel excluded) is about \$0.275 per 190 proof gallon. The manufacturing cost, including coal, interest, repairs, depreciation, taxes, labor, etc., ranges from \$0.10 to \$0.17 per gallon of 190 proof alcohol, depending upon the location and efficiency of the plant. This makes a total of from \$0.37 to 0.44 per gallon, which is greater than the price of denatured alcohol or of ethyl alcohol for denaturing purposes before the war. The reason for this is that the grade of alcohol used for denaturing purposes is not as high as the best that can be produced from grain.

The better grades, which have been redistilled a number of times, and also passed through charcoal, usually command a sufficient premium so as to make up the deficit incurred in the production of alcohol of a denaturing grade. In addition, the above figures apply more particularly to the production of alcohol which is later sold in the form of whiskey and in which a higher quality of grain is necessary than in the production of straight alcohol. It may safely be assumed, however, that the cost of production of alcohol even from condemned grain varies between \$0.25 and \$0.35 per gallon.

One gallon of molasses yields from 0.45 to 0.48 gallon of 190 proof spirit. The price of molasses has averaged from \$0.05 to \$0.075 per gallon, although since the war, and particularly on the west coast, quotations on molasses have gone up as high as \$0.10 per gallon. So that the cost of raw material in a gallon of molasses spirit has averaged from \$0.10 to \$0.15 per gallon, although at the present time it may be nearer \$0.20 per gallon. The cost of production of molasses spirit is slightly less than that of grain spirit, but in either case we have a comparatively high cost of raw material.

One ton of dry coniferous sawdust or other form of waste (or its equivalent on an air-dry or green basis) will yield from 15 to 25 gallons of 190 proof spirit. This material in the vicinity of a sawmill or other large wood working plants is, in some cases, an item of loss, since most of the mills produce waste in excess of their own power requirement. In other cases it is not worth more than \$0.30 to \$0.50 per ton, which, therefore, makes the price of raw material in a gallon of ethyl alcohol from sawdust about \$0.02. This also includes a fuel charge, since the residue after conversion and extraction is available for fuel, whereas in grain and molasses distilleries about seven tons of coal are required per thousand gallons of 190 proof spirit. In grain distilleries, however, the still slops which contain all of the protein and nitrogen that was in the grain are recovered and used for cattle foods, either in feeding pens in connection with the distillery or else are dried and sold as such. This forms a valuable by-product which is not obtained in distilleries operating either on wood or on molasses.

If the manufacturing costs of producing ethyl alcohol from wood can be reduced to a figure approximately the same as the cost of production from grain or molasses, we have a large margin in the cost of raw material in favor of the alcohol from wood waste. Of course, if we compare a yield of 20 gallons to the ton from wood to 80 gallons per ton from corn, we see that the amount of material handled in certain parts of the plant producing alcohol from wood will be four times as great as in a grain distillery of equal capacity, thereby increasing the size of the plant and operating costs. The fermenter and still equipment, however, will not need to be larger than in a grain distillery of equal capacity, so that one of the largest items in the production of alcohol has not been increased.

In recent years the production of ethyl alcohol from sawdust has received a great deal of attention and a great deal of money and effort have been spent in its technical development. A number of plants have been built in this country, but one only of them has, up to the present, been considered a commercial success. Because of the importance of the problem of waste disposal to the lumber industry and because of the adaptability of this process to the disposal of coniferous wood waste in quantity, the Forest Service has investigated both the process and, as far as possi-

*The price of grain increased in 1918. According to the Chicago Board of Trade, the average price of No. 2 yellow corn, 1913-1914, ranged from 19¢ to 21¢ per bushel.

ble, the plants that have been built in an effort to determine the causes for failure and to aid in its development to a commercial success.

Outline of Processes

The processes used for the production of ethyl alcohol from wood may be grouped into two general classes—first, the hydrolysis or conversion of the wood into fermentable sugars by the use of dilute mineral acid as a catalyst; and second, solution processes in which the wood is dissolved from concentrated acid with a subsequent hydrolysis or conversion of the diluted solution.

Processes of the second class involving the use of concentrated sulphuric acid in which the wood is actually dissolved have not received commercial attention because the amounts of acid used have been so large compared to the processes in which the acid is used merely as a catalytic agent that the large initial and recovery cost for acid have prevented commercial development.

The first process of producing ethyl alcohol from wood consists in general of digesting the sawdust, or hogged and shredded waste, with dilute sulphuric acid at a steam pressure of 60 pounds or more for a short time. This is done in rotary digesters which will thoroughly mix the acid and wood. These digesters are of steel boiler plate with an acid proof lining. A part of the wood is converted into a mixture of sugars, some of which are fermentable. The digested material is next transferred to a diffusion battery similar to that used in the extraction of sugar from sugar beets or dyes from dyewood, and here the sugar and other water-soluble material is extracted with hot water from the digested sawdust. The acidity of the extract is then neutralized with lime or limestone, and the sludge formed by the calcium sulphate and some of the dust carried in the extract is allowed to settle out, which requires ordinarily from 15 to 20 hours. The clear solutions are then drained off and cooled to the proper temperature for fermentation. The fermentation, distillation and rectification of the alcohol are accomplished in the usual manner very similar to the production of alcohol from molasses.

History

The first recorded attempts to produce sugar and alcohol from vegetable fiber were those of Braconnot in 1819. From that time on at numerous intervals other work was published and a number of experimental plants were built, although all of them resulted in failure. This was because the scientific basis for the process had not been worked out. In 1898 Simonsen published the results of his research on the subject, in which he investigated both sulphite cellulose and sawdust in a systematic way. As the hydrolyzing agent he used sulphuric acid and from his results concluded that the best conditions for the inversion of sawdust were as follows:

Time of cooking	1 hour
Acidity	0.5 percent sulphuric acid
Proportion of wood to dilute acid	1 to 4
Cooking pressure	3 atmospheres

The above conditions gave him a yield of alcohol equal to about 6 per cent of the dry weight of wood used. Simonsen, however, made but few fermentation experiments, and therein his work was scientifically weak. A small plant was built in Christiania, but did not work out successfully, chiefly for the reason that such a large volume of dilute acid was used which required an excessive amount of steam to heat the charge and which later gave them liquors which were too dilute to distill economically. A number

of other workers checked Simonsen's work from the scientific standpoint and showed that in general the yields he claimed could be obtained.

Some time later A. C. Classen developed a process in which sulphur dioxide was used as the hydrolyzing agent. Classen took out a number of patents covering the various phases of his process in which both gaseous sulphur dioxide and also the gas dissolved in water to form sulphurous acid were used. This process is of particular interest since it was the beginning of the American development of the production of ethyl alcohol from wood, when in 1903 the patent rights for America were acquired by a Chicago company. This company erected an experimental plant at Highland Park, Chicago, and after demonstrating the process to their satisfaction erected a plant at Hattiesburg, Mississippi, at a cost of about \$250,000 to operate on longleaf pine sawmill waste.

This plant was a failure because of a number of mechanical and technical reasons, the chief of which are as follows: First, the length of time necessary to hydrolyze the wood, this requiring from four to six hours; second, the quantity of acid needed; third, the prolonged action of so much acid and water in the rotating digester reduced the wood to a very fine powder and formed much sulphuric acid, which acted on the sugar and other substances present to form gums and caramels and so made the complete extraction of the sugars from the residue very tedious and expensive; fourth, the digester was lead lined and the buckling and breaking of the lining necessitated repairs after every two or three cooks, which proved a great source of delay and expense.

Ewen and Tomlinson, who were associated with the Classen process, began experimenting along new lines in order to overcome the difficulties which were brought out at Hattiesburg. Instead of using an aqueous solution of sulphur dioxide, the gas was passed into the digester along with steam, which furnished, therefore, both the heat and moisture required.

Somewhat later, however, Ewen and Tomlinson gave up the use of sulphur dioxide and were granted a patent covering the use of sulphuric acid as the catalytic agent. A study of this patent and the process patented about 15 years previously by Simonsen will disclose a remarkable identity as to ideas.

Ewen and Tomlinson, who were then the engineers and technical advisers of an alcohol company, erected a plant at Georgetown, South Carolina, for the demonstration of their process. This plant was later acquired by a powder company, which has operated it intermittently for the last three or four years. The sawmill in connection with the alcohol plant burned down in 1913 and was replaced by a large new mill, which was put into operation about a year later. During this interval the powder company devoted a considerable amount of time and money to research on this problem.

Several years ago western capital erected a plant at Port Haddlock, Washington, on Puget Sound, for the production of ethyl alcohol and cattle food from sawdust obtained from mills at Seattle, Tacoma, Everett, Anacortes and Port Blakely. The plant was equipped with six digesters of the same size and type as those that were developed in France by the Compagnie Industrielle des Alcool de l'Ardeche. These digesters consisted of a steel cylinder 2½ meters in internal diameter by 21.3 meters in length, through which were spaced 22 tubes 160 millimeters in diameter.

Outside of each end of the tube heads are flanged boiler steel jackets, one to receive the live steam from the boiler and the other to take off the condensed steam, the heating being indirect, the idea being to save steam by means of the indirect heating. Sawdust and enough water were added through a man-hole into the space between the tubes to raise the moisture content to about 45 per cent. Anhydrous sulphur dioxide was then added and the mixture was cooked at 75 to 100 pounds pressure.

The cost of conversion was excessive because of the very rapid corrosion of the digesters, the long time necessary to heat indirectly and because the sulphurous acid gas leaked from the digester into the steam space, thereby preventing the use of the low pressure steam. In addition, the extraction equipment was inefficient and out of date. The buildings of the plant were excellent and expensive and much of the equipment was imported from France at a large cost.

The extracted sawdust (which had only from 50 to 60 per cent of the sugar formed extracted from it) was mixed with Hawaiian molasses and was put on the market as a cattle food. It was necessary to dry the extracted material down to about 12 per cent moisture in order to prevent decay and this gave great difficulty due to explosions of dust in the dryers. In addition, the plant was located about 80 miles from a railroad, which greatly increased transportation charges, and these facts, coupled with the very poor design and equipment (especially digester and extraction equipment), were no doubt the prime reasons which caused the failure at this plant.

After disposing of the Georgetown plant to the powder company the alcohol company referred to above underwent a reorganization. A large amount of foreign capital was introduced and a large plant designed to produce 5000 gallons of 190 proof alcohol per day was erected at Fullerton, Louisiana. This plant, to our knowledge, has never operated at capacity or even continuously for any length of time. The plant appears to have cost much more than it should. Even at present it is questionable as to whether or not a number of the units in it are of the size and type to secure maximum efficiency. Because of the fact that the plant was built largely with foreign capital the war has interfered with changes that are necessary and advisable before resuming operation, and the plant has been idle for a very considerable period of its existence.

This short outline is merely a review of the four plants that have been built in this country, only one of which has achieved any measure of commercial success, and does not take into account the very large amount of scientific work that has been done in the last decade and which will be covered fully in a later bulletin to be issued by the Department of Agriculture. The powder company, through its development department, and especially by the work of its superintendent and chemist at Georgetown, has really attempted to investigate the problem in a scientific way. Some of the other plants, especially the one in the West, were built by men without full knowledge of the requirements of an operation of this type, and apparently no technical supervision was obtained to assist and direct the work.

As long as the development of this process, which requires the highest type of engineering and chemical skill, is left in the hands of concerns interested chiefly in the disposal of stock the production of ethyl alcohol from wood will be costly to those who invest in it. In view of these facts the following

outline of plant equipment and operation with cost estimates has been prepared so as to present to the lumberman the actual requirements of an industry of this type.

Plant Requirements

The essential parts of a plant necessary to produce ethyl alcohol from wood considered in the order of their use are the following:

1. Adequate sawdust storage.
2. Disintegrating equipment { Hogs.
Screens.
Shredders.
3. Sawdust storage above digesters.
Acid storage.
4. Digesters.
5. Diffusion battery.
6. Neutralizing and settling tanks.
7. Coolers.
8. Fermenters and yeast equipment.*
9. Beer still.*
10. Rectifying still.*
11. Bonded warehouse.*
12. Boilers and engines.
13. Laboratory and office.

*These items must be under U. S. Int. Rev. Dept. approval and supervision.

SAWDUST STORAGE

Adequate sawdust storage will vary with the location and continuity of operation, the sawmill, and the character of the logging operation. The operation of the alcohol plant and distillery must be continuous. The storage must be sufficient to permit compliance with the necessary regulations of the Internal Revenue Department regarding the operation of distilleries. The latter are surveyed as to their output and must produce daily the amount required in this survey or else are penalized with the tax on such a quantity of alcohol as is necessary to make up the survey.

In general, therefore, the alcohol plant should have at least a 15-days' supply of wood on hand and, where logging operations are such as to require frequent shut-downs, the alcohol plant should have sufficient material in storage to last twice as long as the usual shut-downs. The waste can be stored and handled easiest in the condition ready for use, that is, hogged and shredded. Protection from the rain is sufficient and any type of open, walled, but covered building would answer the purpose.

Belt conveyers can be used to handle the material and a long open covered shed, with an inclined bottom sloping into a trough, similar to those used for the storage of sugar beets would answer the purpose.

DISINTEGRATING EQUIPMENT

This would consist of hogs or chippers and shredders and screens. A chip $\frac{1}{2}$ in. long with the grain will be penetrated thoroughly with acid, but the ease with which the sugar can be leached out is a problem that would require attention. However, since the residual digested sawdust or waste left after extraction is ample for power production, and all engine exhaust steam can be used for heating and distillation purposes, the extra power required to chip down a $\frac{3}{16}$ or $\frac{1}{4}$ -in. chip would not be prohibitive and the greater efficiency of extraction would probably make it very desirable. After screening and reshredding the screenings the fine stuff would go by belt to the loading bins over the digester.

SAWDUST AND ACID STORAGE

The loading bins should be of sufficient size to act as an intermediate storage for the material as it comes

from the screen on its way to the digester. They should hold four or five digesters full each and should be placed over the digester and tapered down so that the material can flow directly into the digester similar to those in use in chemical pulp plants.

The acid would come to the plant in concentrated form so as to permit tank-car shipment and storage in steel tanks. The concentrated acid would be pumped into a lead-lined tank above the digester and diluted so that the dilute acid could flow into the digester along with the sawdust. If rotating digesters are used no special mixing apparatus will be necessary, at least we have never found evidence of appreciable quantities of uncooked material when handled in this way.

THE DIGESTERS

The digesters should be rotating and may be spherical or short and cylindrical with dished ends. If the latter type is used the diameter should be double the length of the cylindrical section so that it may be filled as completely as possible. A number of satisfactory acid-proof linings are obtainable at present. During cooking the mass shrinks in volume and settles so that the final volume is only about two-thirds the original volume and leaves ample room for thorough mixing during cooking.

The sizes of the digesters will be governed by the daily capacity of the plant, the heating period and the time of the complete cooking cycle per digester. If the heating period is 15 minutes out of a total of 1 hour for each cook, four digesters, or multiples of four, should be used, whereas if the heating period is 20 minutes out of a total of 1 hour only three or multiples of three should be used. In this way the steam load on the boilers will be as uniform as possible and the boiler capacity will be dictated largely by this load, since the rest of the load for power and distillation purposes will be generally constant. In addition, the hogging, shredding and digester capacity of the plant should be such that it will give sufficient digested sawdust in 18 or 20 hours to run the rest of the plant 24 hours, thereby giving time for repairs and breakdowns.

The cooked sawdust can be discharged merely by rotating the digester and falls into a bin which receives the cooked material from all the digesters and from which it goes by a mechanical conveyor to the different cells of the diffusion battery.

DIFFUSION BATTERY

Closed cells similar to those used for the extraction of sugar beets or dyewood chips can be used. These should be lined so as to be acid resistant like the digesters and the top and bottom should be arranged so that charging and discharging can be readily accomplished. Cells of this type can be obtained in which the extracted material will empty itself after a release of the bottom of the cell. The temperature of the extracting water should be from 75 to 90 deg. C., since this will give not only a greater solubility than colder water but will also sterilize it and will keep the juice sterile while it is settling after neutralization.

The size of the cells and the number of cells in the battery and the amount of water per cell will be governed by the size of the plant and the size of the material that is cooked, since sawdust, for instance, will extract more readily than larger material. As our leaching experiments have shown, seven or eight extractions seem to be necessary; this would require eight or nine cells in the battery, since one is being discharged and filled all the time. Since the sugars are readily soluble, only a short extraction period is necessary, that is, from 5 to 10 minutes on each cell, or a total extraction period of from 50 to 75 minutes. This time, how-

ever, will be governed in part by the length of time that it takes the water to drain through each cell, which in turn depends on the size of the cell. The cells should not be too large, or the extracting water will not pass through the material easily, and the amount of water used should be such that the resulting extract is of the proper concentration for fermentation, which is from 11 to 12 deg. Brix. The Brix will go up another degree on neutralization.

Just as in the case of laboratory extractions, or washing of precipitates, a large number of extractions or washings with small amounts of liquid will give a better extraction or more thorough washing, and a more concentrated extract, than fewer extractions with larger amounts of extracting water for each extraction.

NEUTRALIZATION AND SETTLING

After extraction the acid extract is nearly neutralized with solid or milk lime or a high grade limestone (a magnesia stone is undesirable) and is then allowed to stand so as to settle out the sludge of calcium sulphate. This usually requires from fifteen to eighteen hours so that adequate tank capacity is required here.

COOLERS

The clear juice is then drawn off and passed through coolers to reduce its temperature to about 27 deg. C., from which it goes into the fermenting tanks. The coolers should be of copper and their size will depend upon the temperature of the water supply available.

FERMENTATION, DISTILLATION, ETC.

A 96-hour fermentation period is permitted, so that a four-day fermenter capacity is required. The size of the individual fermenter will be dictated largely by local conditions, such as mean temperature, and the other equipment is the standard distillery equipment in use at present in grain or molasses distilleries.

POWER REQUIREMENTS

The steam load of the plant will be distributed about as follows:

	Per Cent
Pumps	20
Boiler	20
Fire	20
General water supply	20
Beer	20
Alcohol	20
Digesters	20
Hogs and shredders	20
General power from driving conveyors, digesters, etc.	15
Distillation and rectification	15*

*Including all exhaust steam not used for heating boiler feed and extraction water. If large quantities of exhaust are not available, distillation and rectification may require as high as 40 per cent of the total load.

A large supply of pure cool water is necessary. It should be pure for boiler and extraction use and should be cool for use in cooling and condensing. The disposal of the beer still slops requires attention because of the large amount of pentose carbohydrate, and also of dead yeast which is highly nitrogenous and which would lead to rapid putrefaction.

COSTS

The production of alcohol by this process has up to the present time with possibly one exception, as outlined before, not been a commercial success. With new developments at the Forest Products Laboratory, allowing the necessary manufacturing losses involved in extraction, in the sludge of the settled juice, and in distillation and rectification losses, which combined should not be 20 per cent of the total yields, a yield of over 20 gal. per dry ton has been obtained.

Assuming this yield and a location where the supply of waste is uniform and constant for a period of twenty years and where plenty of good water may be had, and

where there is a fairly close supply of sulphuric acid and lime, the cost of alcohol from wood in a properly designed and constructed plant of 2500 or 3000 gal. per day capacity, is estimated per gallon of 190 proof as stated in Table I.

TABLE I

Yeast nutrients	\$0.015 to \$0.020*
Repairs and materials (exclusive fuel and wood) ..	0.030 to 0.040
Labor	0.015 to 0.030
Wood and fuel	0.020 to 0.030
Interest at 7 per cent.	0.019 to 0.029
Depreciation at 10 per cent.	0.023 to 0.035
Overhead, taxes, etc.	0.015 to 0.030
Total	\$0.137 to \$0.195

*This item may go as high as \$0.035 in some sections since the war, also rapidly advancing prices of iron, steel and copper. Particularly the latter, will require some increase in the above estimate, which was figured for market conditions existing over a year ago.

In Table I wood has been valued at \$0.40 per cord of 1800 lb. of dry wood per cord. This should consist of sawdust and hogged refuse but should not contain over 10 per cent of bark, since the yield of sugars and alcohol from bark is very low. A large quantity of bark would mean running a large volume of inert material through the alcohol plant at considerable expense without return and in the case of most barks would add large quantities of undesirable tannin to the solutions to be fermented.

Before the war alcohol for denaturing purposes could be obtained in quantity for \$0.30 per 188 to 190 proof gal.; at present (June, 1916) the market value runs as high as \$0.67 per gallon for small lots with, no doubt, appreciable shading for contracts in quantity. The price, however, has gone up from 33 1/3 to 50 per cent and as long as the war continues no appreciable decrease in price seems probable because of the demands for grain and molasses for other purposes and because of the enormous amounts of alcohol being used. Before the war from 10,000,000 to 11,000,000 gal. of denatured alcohol were being produced annually. This production has now increased to over 30,000,000 gal.

Under normal operating conditions most mills, particularly the large ones, produce waste in excess of their own power requirements and in large mills equipped with efficient power plants this excess will be from 50 to 65 per cent of the total produced. The disposal of this waste by means of a burner is, therefore, almost invariably necessary. The cost of burning this waste varies widely with the size and efficiency of the mill, but from figures gathered by this laboratory this expense ranges from \$0.30 to \$0.66 per cord, or from \$0.11 to \$0.22 per 1000 ft. on all of the lumber cut, and means that the present cost of waste disposal amounts to about \$6,000,000 annually, in addition to the value of the wood so burned.

All waste, therefore, that could be disposed of for the production of alcohol would not only net the sawmill about \$0.40 per cord but would also relieve them of the charge of burning which, as given above, ranges from \$0.30 to \$0.66 per cord and which, therefore, practically doubles the above realization to the sawmill.

In other words, an operation of this kind in conjunction with the sawmill would add from \$0.22 to \$0.45 per thousand to the value of all lumber cut. This applies particularly to mills cutting coniferous species to which the above alcohol yield and waste disposal figures apply.

From work going on at present, it seems that the yields from some of the hardwoods will not be as great as those obtained from the coniferous species.

In conclusion, the successful production of ethyl alcohol from sawdust seems to depend upon the proper design, equipment, and management of the plant, rather than its chemical or fermentological features. Large volumes of low grade materials must be handled

quickly and efficiently under unusual technical conditions. The perfection of the necessary acid-resisting pieces of apparatus, along with the experience of the plants that have been built, together with the utilization of material whose mere removal at present is an expense justifies a serious consideration of the future of this industry.

Forest Products Laboratory,
Madison, Wis.

The Flotation of Minerals*

BY ROBERT J. ANDERSON

During the past 5 years no subject has aroused more interest or received more attention among mill operators than flotation. One reason for this is, undoubtedly, the remarkable success of the process in Australia where that country has risen to the position of furnishing one-fifth of the world's supply of zinc. The plant of the Butte & Superior Copper Co., designed by James M. Hyde in 1912, was the first important large flotation plant in this country; other installations have been made since then with considerable frequency, particularly so in the last 2 years.

Without going into complete detail, it may be safely said that although flotation is a highly successful commercial process, it is more or less on an empirical basis. Upon scanning the literature, it is found that the flotation investigations have, in the main, dealt with a solution of the problems which accrue to practice; until recently no attempt was made to remove the difficulties in the way of the formulation of a consistent and harmonious theory. Of late this phase of the work has been receiving considerable attention, particularly by the United States Bureau of Mines at its Salt Lake City station, by the Mellon Institute at Pittsburgh, by the General Engineering Co. at Salt Lake City, by many of the mining schools, and private individuals almost *ad infinitum*. There is, at present, an enormous amount of laboratory work being carried on in flotation research, and probably the time is not far away when a generally acceptable explanation of flotation phenomena can be set forth. However, at this time, it seems as though the current technology is befogged with a superabundance of contradictory evidence; this confusion can only be dispelled as time proceeds and the knowledge of the subject becomes more complete.

Many phenomena are supposed to contribute to the flotation of minerals, whether in whole or in part is a mooted question. I shall only sketch roughly the present tendency of ideas and make no reference to the first early and crude notions which have little value other than historical interest. Many questions have arisen in connection with flotation concerning such matters as surface and interfacial tensions, adsorption, absorption or occlusion, colloids, emulsions, electrolytic and electro-static phenomena, etc. These phenomena are to be discussed in later paragraphs in order to ascertain what bearing they may have, if any, on froth flotation. No final solution of this very large problem is attempted in this paper, for in any discussion of flotation theory, at this time, one is confronted by so many obstacles that at best only a rather fragmentary presentation can be made. An attempt has been made in this writing to correlate the operative and fundamental principles and compare in a measure some of the theories so far advanced.

Discussion of Certain Factors

SURFACE AND INTERFACIAL TENSION

Surface tension has been rather well defined in arti-

*A paper to be presented at the Arizona meeting of the American Institute of Mining Engineers, September, 1916.

cles appearing in the *Journal of the American Chemical Society* during the years from 1908 to 1913. The theory of surface tension has been treated in particular by Laplace, Gaus, and more recently by Van der Waals, and by Willows and Hatschek.¹ As defined by Jones, "potential energy, present at the surface of liquids, produces a tension which is known as surface tension." The phenomena which are invariably indicative of surface tension are commonly observed: Drops of a liquid not exposed to an external force, *i.e.*, either suspended in another liquid of the same specific gravity or freely falling, assume a spherical shape, the sphere being that form of body with the smallest surface per given volume; further, if water be placed in an open vessel its surface film will be a measurable quantity, and its thickness will vary with a number of factors of which temperature is one. Its thickness is observed as ranging from 4×10^{-5} cm. to 4×10^{-3} cm., and its density, when referred to the main bulk of the water below, will approximate 2.14. Surface tension is not affected by the surface area. It is numerical in value and expressed in dynes per centimeter. It is a variable factor dependent on temperatures, increasing numerically with falling temperature, *e.g.*, water at 18 deg. C. has a surface tension of 73 dynes per centimeter, and at 0 deg. C. 75 dynes per centimeter. At the critical temperature of a liquid its surface tension becomes nil.

All liquids have a definite cohesion or tensile strength, which is ascribed to the well-known mutual attraction of their molecules. This then is comparable to a pressure existing within a liquid, which has been termed the "intrinsic" pressure. Naturally the value of the surface tension of solids is numerically a high one. The surface tension of a pure liquid against its vapor can be and is markedly affected by the addition of soluble contaminants. Some salts will raise the surface tension of water while others will lower it; the fact that the salts of weak acids will lower the surface tension of water is explained by the fact that free acid is liberated by hydrolysis. It is further known that all acids will lower the surface tension of water. The surface tension of water is decreased by the addition of oil, or better, oil will reduce the interfacial tension between the water-air phases. A phenomenon for which no explanation has been given is the one which shows that the addition of contaminants may either raise or lower the surface tension of water, but such addition, while it may decrease that tension greatly, can increase it only slightly. Any lowering of surface tension is more marked in a liquid which has a high surface tension, *e.g.*, water, than in liquids of low surface tension.

There can be, of course, no surface tension without adsorption, which produces, in the case of positive adsorption, an increased concentration resulting from a lowering of the surface tension by the contaminating and dissolved substance whatever it may be. The equation of Gibbs— $u = -c R t d\sigma/dc$ —gives the relationship between surface tension and the distribution of the solute between the bulk of the liquid and the film interface. Here the notation is:

- u = excess of substance in the surface layer,
- c = concentration in the main body of the liquid,
- R = the gas constant,
- t = absolute temperature,
- σ = surface tension.

This shows that when the surface tension is reduced by the addition of a contaminant, the quantity $d\sigma/dc$ is

negative and u is positive (from algebraic consideration). The surface film then contains more of the contaminant than the main body of the solution. If the surface film contains less of the contaminant than the main body of the solution it is a case of negative adsorption.

As given in the foregoing, the surface of a liquid against its vapor is in tension—surface tension; the surface of a liquid against another liquid, or a gas or solid, is also in a state of tension: this is termed interfacial tension. In the consideration of the bearing which surface and interfacial tensions have on froth flotation, this condition of affairs obtains in the flotation machine: Pulp consisting of ore of approximately 80-mesh, water in ratio of 3:1 of ore, and oil in disappearingly small amount, is being violently agitated. For the sake of a specific case, the air is being forced mechanically into the swirling pulp by beaters or stirrers. These phases then are present in flotation by the oil-froth process, *viz.*, solid-liquid (ore-water), solid-liquid (ore-oil), solid-gas (ore-air), liquid-liquid (water-oil), liquid-gas (water-air), and liquid-gas (oil-air). Thus six tensions are present, but if the oil is soluble in the water the tension number becomes three. It is known that pure water can not be made to maintain a persistent froth because its surface tension is too high. Acid, if present, will lower the surface tension of water, as will oil if it is soluble to any extent. Very many interesting and important, as well as speculative, consequences follow from a consideration of interfacial and surface tensions, and, in a later paragraph, we shall have occasion to return to the consideration of these complicated phenomena.

Certain metallic sulphides, *e.g.*, galena, have the power of floating on undisturbed water; they are not wetted and the curve of contact is convex. Some gangue minerals, *e.g.*, quartz, possess an adhesive force of attraction for water which exceeds the intrinsic pressure of the water; they are therefore wetted and sink to the bottom, being drawn through the surface film. Such properties of the minerals are affected by the presence of oil, acid, and other reagents. Oil has a greater adhesive attraction for sulphide minerals than for gangue minerals; and the addition of acid and oil (if it is soluble) acts as a contaminant which will lower the surface tension of the water and aid in the production of a persistent froth. Let us now look into the question of adsorption and see what part it plays in flotation, since it is so requisite to the production of a variable surface tension.

ADSORPTION.

Generally speaking, adsorption deals with the unequal distribution of substances at the interface between dissimilar phases such as, solid-solid, solid-liquid, solid-gas, liquid-liquid, liquid-gas, and gas-gas. It is purely a physical effect. Commonly, adsorption² is construed to be the result of the condensation of a disperse phase upon the interfacial boundary solid-liquid. Returning for a moment to the Gibbs equation mentioned above, adsorption may occur if the interfacial tension solid-liquid is reduced—this being positive adsorption. If, however, such an interfacial tension is raised in value it is a case of negative adsorption as the solute or disperse phase will be rejected from the surface. Any condensation, strictly stated, of a solute or disperse phase in the interfacial boundary separating liquid-liquid or liquid-vapor is held to be a special case of adsorption. However, in the general sense, the phenomenon is looked upon as being the

¹Willows and Hatschek: *Surface Tension and Surface Energy*, 1917.

²Jones: *Elements of Physical Chemistry*, 1907.

³Reynolds: *Transactions of the American Chemical Society*, Vol. XIX, No. 1, p. 1 (March, 1915).

result of condensation of a disperse phase in the interface of two immiscible phases. Adsorption is shown very strikingly by colloid gels—the product obtained by the coagulation of sols—and certain cases of selective adsorption are very remarkable. Adsorption will naturally vary with the surface exposed. In Miss Benson's experiments with amyl alcohol in aqueous solution, amyl alcohol reduced the surface tension of the water, and it was found by producing a voluminous froth that the alcoholic concentration in the froth exceeded that in the bulk of the aqueous solution by about 5 per cent. A froth has a very large surface, and it would be expected that the adsorption would be greater. Such experiments prove the value, qualitatively, of the Gibbs rule.

Recent work shows that all solids do condense certain amounts of gases on their surfaces and retain them there with very great tenacity. Liquids in like manner adsorb gases. Further, liquids and solids exhibit marked selective adsorption of gases. Although this selective adsorption obtains, no evidential proof has been submitted which says that the amount of gas adsorbed by one substance is largely different than the amount adsorbed by another substance. An electric charge on an adsorbed substance probably would considerably influence the amount adsorbed. The adsorption of air plays an important rôle in flotation, for as Breuer points out, the adsorbed air film is enormously responsible in preventing the coalescence of solid particles.

A comprehensive study of the adhesion of small particles of solid to the dineric interface (surface separating two liquid phases) has been made by Hofmann,⁴ based on the theory of Des Coudres.⁵ From the standpoint of flotation this may be given as follows: If a solid particle, *e.g.*, quartz, is wetted much more strongly by water than by another liquid, *e.g.*, oil, the water will displace the oil, and a film of water will form about the quartz particle according to the relative forces of adhesion. Then the quartz particles will remain in the water phase if the water has a specific gravity greater than the oil, regardless of their size; but if now the oil has a greater specific gravity than the water, then the quartz particles will remain in the water phase until the size of the particles is such that the force of gravity will remove them from the water. Conversely, if a solid particle, *e.g.*, galena, is wetted more strongly by oil than by water, the oil will form a surface film about the particle and hence prohibit the particle from being wetted by water, *i.e.*, from entering the water phase. Then the galena will only enter the water phase when the water is more dense than the oil, and, further, when the galena particles are of such a size that the force of gravity overcomes the adhesion of the oil film to the oil.

Returning to purely theoretical considerations, Hofmann draws certain conclusions at this juncture which deal with the supposition that solid particles will then remain in the surface separating two immiscible liquids, if those particles are wet partially by each liquid. I quote Bancroft at length on this matter:⁶ "The solid particles tend to go into the water phase if they adsorb water to the practical exclusion of the other liquid; they tend to go into the other liquid phase if they tend to adsorb the other liquid to the practical exclusion of the water; while the particles tend to go into the dineric interface in case the adsorption of the two liquids is sufficiently intense to increase the miscibility of the two liquids very consider-

ably at the surface existing between solid and liquid."

Any simultaneous adsorption of two immiscible liquids by a solid would probably tend to result in the formation of a homogeneous liquid phase at the surface of the solid.

In regard to the effect of contaminants or other impurities in contact with two immiscible liquids, this condition obtains: If the contaminant is soluble in one liquid but not in the other, and also lowers the interfacial tension of the two, the equation set forth by Gibbs exacts the requirement that the contaminant should obtain in the interface. Examples of this prove the validity of the law.

The terms adsorption and absorption have been used interchangeably in some writings, thus contributing to the already existing confusion of ideas.

ABSORPTION OR OCCLUSION.

There are three ways by which gases can be held with reference to solids: *viz.*, (1) By surface adsorption; (2) in solid solution; and, (3) by occlusion. The term "occlusion" has been applied indiscriminately to any of these above methods by which gases are held by solids. Strictly speaking, by occluded gas is meant gas which is adsorbed and held in finely divided pores or openings which may be of microscopic size.

A recent theory⁷ holds that occlusion plays the operative rôle in the flotation of minerals by all processes. I am unable to reconcile myself to this explanation for a number of reasons. Marked instances of occlusion at normal temperature are known only in certain amorphous substances like charcoal. Many metals, of course, both in the liquid and solid states, have the power of occluding gases, often in marked degree. There may be and undoubtedly are fine pores in the floatable minerals, which may in a sense be considered as an assemblage of capillary tubes; these can and do occlude gas. Yet occlusion is marked only in amorphous substances and in certain metals as just stated. It is definitely known that occluded gases are retained with very great tenacity by the substances occluding them and therefore expelled only with difficulty. It seems anomalous then to hold that the occluded gas can depart from the mineral occluding it with sufficient speed to aid the air bubbles in the liquid in the process of flotation.

I believe rather firmly that occlusion is not a cogent factor in flotation by any process, and that a more consistent theory may be formulated without postulating these conjectures regarding occlusion.

COLLOIDS.

Colloids, in the original definition of the term by Thomas Graham, are not a definite class of substances; rather a large number of different substances may be made to assume the colloidal state if proper precautions are taken. All of which reveals the striking fact that this colloidal condition is a *state* and not a *form* of matter. The ultra-microscope of R. Zsigmondy and H. Siedentopf has increased the knowledge of colloids to a great extent. A rather general statement may be made regarding colloids and that is, that they do not show osmotic pressure in any appreciable amount. Colloidal solutions—sols—are regarded as systems of two phases, in which the dissolved substance is the disperse phase and the solvent the continuous phase.

Since in flotation the ore is often as small in size as certain of the colloids, the flotation pulp, (ore, water, etc.) can be looked upon as a coarse suspension, and the laws of colloids apply here with equal force as in

⁴*Zeit. Phys. Chem.*, Vol. 1, 88, 111, p. 385, 1913.

the realm of colloidal chemistry. So-called suspensions are systems consisting of solid particles of microscopic size distributed through a liquid. As mentioned by Ralston,⁸ Reinders has treated at length the particular case of a solid phase maintained in contact with two liquid phases, i.e., two immiscible liquids. His work is based on the different interfacial tensions existing, and his experiments and those of Hofmann, as mentioned in an earlier paragraph, have considerable bearing on the flotation problem.

EMULSIONS.

Emulsions are fairly coarse dispersions of one liquid in another with which it is immiscible. The simplest and commonest emulsions are the oil-water emulsions, i.e., the pure oil-water emulsions, containing no emulsifying agent such as soap, proteids, etc. In such systems the oil globules can be coagulated by electrolytes, show the Brownian movement strikingly, and can even be retained by some filtering media. Any process of emulsification is dependent on a surface tension lowering, or, to be more precise, on a lowering of the interfacial tension between the two phases. According to Briggs and Schmidt,⁹ the two essential requirements of an emulsifying agent are these: (1) The property of condensing by adsorption in the dineric interface; and (2), the ability to form under these circumstances a strong coherent film. Temperature is a cogent factor in emulsification, for its effect is to reduce the interfacial tension between phases and also to lower the viscosity of the phases. In the production of emulsions, a considerable amount of surface energy is produced because of the relatively large surface area of the disperse phase; an emulsion is the more speedily effected if such surface energy be reduced by the use of a liquid having a low surface tension as the continuous phase. Some emulsions, under certain conditions, display a great increase in viscosity over that of either of the immiscible phases, e.g., the emulsions of the Pickering order—up to 99 per cent of oil in 1 per cent of soap solution—can be cut into cubes. Any emulsion produced with soap solution is at once rendered nil by the addition of acid as the latter will decompose the soap.

If solid particles are suspended in a liquid, they tend to increase the viscosity of that liquid only gradually depending on the amount of solid particles present. Experiments have shown that whenever a substance which is in suspension is wetted by two immiscible liquids simultaneously, it will go into the dineric interface in the manner already referred to, and will therefore tend to produce an emulsion. If, however, the suspended particles can not coalesce due to adsorbed oil film or for other reasons and thus effect the production of a coherent film, the emulsion will not be stable. Very little data are available on the production of emulsions by the oils used in flotation work, or on the matter of interfacial tensions between such oils and water. However, we are no doubt dealing with emulsified or partially emulsified pulp in some of the flotation processes, e.g., the oil-froth process at least.

ELECTROLYTIC AND ELECTROSTATIC PHENOMENA.

Any substance which is placed in contact with water or many other liquids will assume an electric charge, the origin of which is, as yet, not set forth. Most substances when in contact with water become negatively charged, but these charges can be differed at will or reversed by the addition of the proper electrolyte in re-

quisite amount. These electric charges are by no means confined to submicroscopic particles but are found also on the particles of a coarse suspension. Gangue minerals, e.g., quartz, when suspended in water, are negatively charged, and sulphide minerals, e.g., pyrite, are positively charged under like conditions. Oil drops are negatively charged, as are air bubbles under certain conditions which will be given subsequently. These charges are very minute when referred to the mass of the particle. Substantial evidence is at hand which goes to show that floatable minerals have the positive sign of electricity when suspended in water or can be made to assume that sign by the addition of proper electrolytes in sufficient amount. As Callow¹⁰ observes, there is a parallelism between electrostatic characteristics and the flotation properties of ores. Many of the electrostatic principles have either been carried too far or misapplied as recent work shows.

Experiments in the realm of colloid chemistry indicate that the contact films are charged and that such charges markedly affect the dispersion or coherence of the particles in suspension. Naturally, oppositely charged contact films will coalesce while similarly charged contact films will repel each other, if the charges are sufficient in amount to overcome the force of cohesiveness; in the latter, dispersion is the result. The oil and air contact films having negative charges would tend to attract the sulphide particles, but further than this possibility electrostatics probably plays little part in flotation for the reasons given in the following paragraph.

As referred to above, it is pretty generally admitted that only minerals which are good conductors are suitable to flotation. Now then, as the electrical theory contends, electrified bubbles must be supplied to float the conducting minerals which are attracted, leaving behind the minerals which are not. The bubbles in flotation are simply air spaces contained by a mantle of oil or water, and there is, therefore, nothing within to bear the charge. In case it could carry a charge, which would only be possible by the presence of contained ionized gases or water vapor, the charge would be speedily dissipated by contact with the interfacial boundary. Then in order for a bubble to carry a charge it must be protected by a dielectric film. Further, electrostatics plays probably little part in holding the sulphide particles and the gas bubbles together as neither the bubble nor the particle can have a charge of sufficient magnitude when referred to the size. The electrical theory has been strongly championed by at least one writer¹¹ and has been tolerated by some others. A recent article¹² indicates that the principles of electrostatics have been considerably misapplied. It is my belief that electrostatics may be a small contributing factor in flotation in a manner not as yet understood because of a lack of data concerning charges at the interfacial boundary between immiscible phases, e.g., where the colloidal state is introduced in oil-water emulsions. Apparently, as far as any data at hand are concerned, they all serve to condemn any attachment of great importance to the electrical theory.

The Character and Formation of Flotation Froth

Bearing in mind the phenomena discussed above, let us turn to the flotation of minerals by means of the froth process and look into the character and formation of froth. A froth has been defined as a multiplica-

ity of bubbles; this seems to be wanting in some respects but will be requisite and sufficient for this purpose. The froth of flotation is formed by the action of air or gas in water containing impurities or contaminants, for pure water will not maintain a froth.

FROTH AND BUBBLES.

The idea has been abandoned of late, by most people, that a low surface tension is the essential requirement for froth formation. As mentioned by Coghill in a recent writing, the contamination of the liquid with an impurity which will cause a variable surface tension is the real requirement. A bubble of air is spherical in shape and this shape can only be maintained if the external pressure exceeds the internal pressure. Since a bubble does not expand *per se*, large bubbles can only be accounted for by heat, coalescence or electrification. Viscosity is an important factor in froth persistence as it increases the tenacity of the liquid film and thus prevents ready rupture. The rupture or bursting of bubbles is accounted for by these reasons:

1. Concussion upon a surface film which is deficient in the requisite viscosity and variable surface-tension.

2. Relief of pressure—here the gas of the bubble in expanding exerts a pressure which exceeds that of the liquid film.

3. Adhesive force of the entrained gas for the atmospheric air.

4. Evaporation of the liquid film.

Flotation bubbles will burst then for any one or a combination of all these reasons.

Solutions in which the continuous phase is a solution of soap, various products from the saponification of albumens, etc., will froth voluminously even in a very diluted condition; frothing never occurs in pure liquids and is a definite proof that the solute or disperse phase lowers the surface tension of the solvent. A froth, which shows adsorption at the interfacial boundary of solution and gas, depends for its persistence on the production of a viscous film at that boundary; these viscous films are the direct result of surface adsorption of the disperse phase, *i.e.*, dissolved contaminants, the amount of which is small—disappearingly so. The work of Hall and of Miss Benson shows that in a foaming liquid the foam is richer in dissolved contaminant than is the bulk of the liquid. Froth formation in the Callow cell is the result of the injection of air into the pulp (already emulsified); the froth continues to obtain as long as there is sufficient air injected into pulp of the proper consistency. The froth in the Callow cell is governed in nature by the kind of oil used and by the amount of air. A pneumatic froth is unstable or ephemeral, *i.e.*, it dies rapidly when removed from the influence of the injected air. The mechanical froth, on the other hand, is thick and persistent, and must be broken up in dewatering the concentrates.

OILS

Oils have a well-marked selective action for metallic sulphides, tellurides and some other minerals. The fact that both the oil and the air or other gas have a selective adhesion for sulphides prevents them from being wetted by water. Conversely, the quartz and other minerals exhibit just the opposite characteristics. The gangue minerals, generally, do not exhibit adhesion for either gas or oil, and hence they are readily wetted by water. Gases have a well-defined adhesiveness for oils; hence the air or gas adheres strongly to the oil film. The stability of a froth depends, in the main, on the kind of oil used, *e.g.*, pine oil makes a weak brittle froth, and creosote makes a stable elastic froth. The

work of Devaux¹ on oil films explains how so small an amount of oil as is used in the various flotation processes can be so efficacious. From a consideration of the immiscible oil-water interface, if any oil will film the internal surface of a gas bubble the sulphide mineral particles would be contained in the oil-water interface no matter what the nature of the gas contained by the water film. The sulphide, if it enters the oil phase, would then present an oiled surface to the water phase. There are three conditions then: (1) The mineral enters the oil phase completely; or (2) the mineral enters the water phase completely; or (3) the mineral enters the oil-water interface.

Some experiments made to determine the nature of the frothing power, selective and collective action of different oils show some interesting results. I made some tests on a zinciferous slime from the Joplin area with different oils and the results obtained indicate that a definite mixture of oils will effect better recoveries than any one oil alone. The best combination consisted of pine oil as a frother, plus wood creosote as a frother and selector, plus refined tar oil as a froth stiffener. The complete results of these experiments will be given in a later paper.

In general, pine oil makes a brittle froth which immediately dies; creosotes make a more elastic froth, the bubbles of which may expand to 3 in. in diameter or more before rupture. Coal-tar products are rather poor frothing agents and if used must be aided by either creosote or pine oil to produce a good froth. Oils of a lubricating nature seem to be of little value as flotation oils, while such light oils as gasoline and naphtha are of value only for thinning the heavy coal and wood tars.

AIR AND GAS

At this time there are three ways by which a gas may be forced into a solution mechanically, *viz.*:

1. By beating it into the solution by means of beaters or paddles—as in the Minerals Separation and similarly mechanically agitated machines.

2. By pneumatic means—as in the Callow cell where the air is divided by the porous blanket bottom into minute sprays.

3. By so-called liquid jets—as in a process recently patented in which the air is introduced as a surface film surrounding a liquid jet by surface tension.

Conversely, there are three methods by which dissolved gas may be expelled from a liquid, *viz.*:

1. When the liquid is supersaturated, the excess gas is expelled.

2. By heating the liquid, when some of the gas is expelled due to an increase in its volume.

3. By pressure reduction, as in the Elmore vacuum process, where, according to the law of Henry, "the amount of gas dissolved by a liquid is proportional to the pressure to which the gas is subjected."

An air or gas bubble on being introduced into a liquid is at once surrounded by a film of the liquid. Such a bubble will rise to the surface (carrying the metallic sulphides by reason of the forces already mentioned) on account of gravitation, by which is understood that the adherence of the air to the liquid is less than the force of gravity.

Résumé

From a consideration of the foregoing, it is believed that the theory based on the different interfacial tensions involved is the dominating one as well as the more consistent at this time. Probably flotation is due to a combination of phenomena which are rather high

¹Devaux, Oil Films on Water and on Mercury. Smithsonian Report of 1913, p. 261.

²Gilman, Elements of Physical Chemistry, p. 177, 1907.

in the scale of complexity. The theory based solely on occlusion goes "by the board" as it has been shown that the contributing effect of this phenomenon has been interpreted rather laxly.¹ The phenomenon of electrostatics may be a small contributing factor but recent work indicates that the principles have been misapplied. An explanation more in consonance with fact can be given in terms of the interfacial tensions involved, without postulating either occlusion or electrostatics, as mentioned above.

The main and essential requirements for froth flotation are: (1) The production of a persistent froth by any means; (2) the attachment of the bubbles of air to the sulphides or other material to be floated; and (3) the maintaining of a selective action of the froth bubbles for the sulphides or other material to be floated.

Why this is accomplished is outlined in the above, particularly under the subhead, "Adsorption." Probably, before any generally satisfactory estimate of the many complex factors, which are supposed to be involved, can be secured, a more thorough investigation of all of them will have to be made than has thus far been attempted. However, in this line of inquiry there has been a steady progression of thought and a remarkable increase in knowledge in the past few years; and the art of flotation will continue to improve and develop as the more complete knowledge of the different factors involved increases and allows the exercise of a better control of them.

Testing the Durability of Pipe Under Corrosion*

BY F. N. SPELLER

All will agree that a service test, or at least a test under service conditions, is the only reliable method for determining the relative durability of iron and steel products. However, to be of any value it must be possible to carry such a test to conclusion in a reasonable time. The so-called "acid test" quickly attracted attention, but as this proved to be misleading the effect has been to discount any attempt to accelerate corrosion. Nevertheless, there are certain conditions commonly found in service where pipe is subject to aerated water at a temperature of 140 to 180° F. under pressure, where corrosion is very severe. The method of testing here referred to works under such conditions, which are more or less common to all water and steam-pipe service.

The main factors controlling corrosion in pipe are:

1. The amount of free oxygen in solution in the water.

2. The volume of flow, which is an important factor, mainly on account of the greater amount of oxygen available; and

3. Temperature. Corrosion increases with the temperature, reaching a maximum somewhere between 160 and 180° F.

These conditions are reproduced in the apparatus shown in Fig. 1. This consists of a tank reservoir open at the top, which may be filled with a supply of any kind of water selected for the test. This water is main-

tained at any desired temperature by means of a small gas heater *B* fitted with a thermostat, or a steam coil may be inserted if more convenient. An ejector is provided at *C* and operated by air under three or four pounds pressure. The air should first be passed through a mass of excelsior or similar material to re-

FIG. 1—APPARATUS FOR CORROSION TESTING, USING AERATED HOT WATER

move oil. The heated water is thus aerated, forced up through the coil of pipe and discharged continuously into the top of the tank. The coil consists of alternate lengths of the materials under test. A glass tube may be inserted in the coil if it is desired to observe the flow. By keeping up a continuous flow in this way at a temperature of 160 to 180° F. the relative tendency of pipe to corrode may be determined in three to four months. The amount of corrosion found in that time with this apparatus will be found equal to about two years under the same conditions in actual service.

The acceleration of corrosion in this apparatus is principally due to the continuous flow and the greater amount of oxygen and carbonic acid which is thereby brought into contact with the interior surface of the pipe. The details of this machine may be altered according to local conditions. If the water is not fresh and almost pure, the supply should be renewed from time to time.

The amount of corrosion in both wrought-iron and steel hot-water supply pipe, as measured by the depth of pitting, will frequently amount to about 0.1 in. in two years. We have found with this apparatus nearly this amount of corrosion in pipe of this kind in three months, with the water circulating at the rate of one to two gallons per minute. The relative depth of pitting is apparently the same in each case.

The writer has used this scheme for two years in research work on the improvement of pipe and pipe coatings, with much saving of time compared with similar tests on pipe in actual use.

Increased Production of Bauxite.—The production of bauxite in 1915 showed an increase of 34 per cent over the 1914 output, due to the great demand for it in the aluminum industry. The production according to the Geological Survey was 297,041 long tons. Only about 1 per cent of the total consumption was imported.

The Theory of the Corrosion of Steel*

BY LESLIE AITCHISON

The problem of the corrosion of iron has been the subject of a great deal of attention during the past twenty years or so. By means of a very large number of experiments, conducted by various workers, amongst whom may be mentioned Sir William Tilden, Messrs. Walker, Whitney, Moody, and Friend, a number of facts have been accumulated, and two theories have been put forward to account for the actual corrosion of iron. In practically all these cases, the material employed has been pure, or nearly pure iron (*e.g.* the iron foil of Kahlbaum), and in most cases the interest has centered round the attack upon this by pure water (that is, frequently distilled water). At the present time the question is an open one, as to the actual details of the corrosion under these conditions, and the present author does not propose to enter upon that particular field.

Most of the workers have left the theory of the corrosion of steel, which is a material of much greater complexity of structure than iron, rather well alone. This particular problem may be attacked, however, quite apart from the one stated above, and although it may be rather premature to define a concise theory of the corrosion of steels, yet the author feels that certain points might be discussed with advantage, as some fair amount of experimental evidence has accumulated. Acting upon this, the author wishes to put forward, with all modesty, the points which follow, in the hope that, even if they are not acceptable to all those who have thought out this problem, they may give rise to the expression of some other opinions, and so help towards the fixing of some precise idea upon this most interesting subject.

The complex structure of steels, composed as they are almost invariably of carbides imbedded in a matrix of some carbon-free material, renders it almost certain that the action going on in a steel during its corrosion is a galvanic one. This conclusion is not seriously at variance with either of the two theories mentioned above as to the essential nature of corrosion. The large number of galvanic couples present in an ordinary sample of steel can be well imagined, and these couples will consist of the carbide on the one hand, and the ferrite or solid solution on the other. This postulates at once that one of the two constituents will be anodic in its action, and the other cathodic. The anodic one will be attacked by the solution—that is, the material composing the anode will pass from the atomic to the ionic condition.

The other material, acting as the cathode, will remain in the atomic (or molecular) condition, and hence will appear to be unattacked. The intensity of the galvanic action between the two constituents will depend, other things being equal, upon the potential difference between the two constituents with respect to the corrosive liquid which is in contact with the steel.

The carbides in all steels, although of varying chemical composition, will be likely to be possessed of very similar electrical properties, and hence it appears reasonable to assume that the electrolytic solution pressure of all the carbides will be the same, or nearly so. On the other hand, the solid solution, which may range from practically pure iron to an alloy containing many per cents of a second element, will be a material of very varying electrical properties. As a result the electrolytic solution pressure of this constituent will change very considerably from steel to steel, and will in consequence produce a considerable variation in the potential difference existing between the constituents of the steel. As a result the corrosion of the steel should vary a great deal with changes of composition.

All investigators have agreed up to the present in regarding the carbides as being electro-negative (that is, as having positive electro-affinity, or a greater tendency to exist in the molecular than the ionic form). Hence their action should be cathodic, and they should not be attacked by the corrosive liquids. That this is so may be seen by microscopic examination. Two typical structures after corrosion are shown in micrographs Nos. 1 and 3 (Plate 1), the massive carbide being quite obvious in the two cases. The first is a pure carbon steel containing 1.25 per cent of carbon, and the second is a steel containing 0.73 per cent of carbon and 21.5 per cent of tungsten.

A similar result is obtained by an investigation of the attack of dilute acid upon various steels. By an analysis of the material which goes into solution, and a comparison of this with the compositions of the carbides separated by other methods, it will be found that the carbides are not attacked, and are left in their original form.¹

As a result of this the carbides in steel may be regarded as acting in two different directions. First of all, they act as resisters of corrosion. Since they are not attacked by the corrosive liquids, there should be a

smaller loss in a steel which is composed largely of carbide than in one which contains only a moderate amount of that constituent. This may be, and probably would be, true, were it not for the other action of the carbides. This is connected with their cathodic action. The intensity of the galvanic action will be to some extent proportional to the area of contact between the two constituents. The more finely divided the carbides, the greater will be the area of the surface of contact; and also the larger the quantity of carbide the greater the available number of surfaces of action.

That this is true may be seen from the figures of Table I. The first pair of results demonstrate the second action, of increasing the carbide, whilst the remaining ones show the first action—that is, of increasing the fineness or the state of division of the carbide. This latter is the normal result of the addition of small proportions of a third element (that is, one besides iron and carbon) to steel.

These three pieces of evidence—the microscopic, the analytical by sulphuric acid, and the effect upon the corrosion—may be taken as conclusive in proving that the carbides act throughout as cathodes. The rest of the material then becomes the anode in the various galvanic couples present in the material. As stated above, this residue of the steel is practically always solid solution. In the case of ferrite, the solution is extremely dilute, sufficiently so for the ferrite, to be termed pure iron, while in other cases there may be as much as 12 or 15 per cent of a second element.

FIG. 1.—GENERAL TYPE OF CURVE GIVEN BY A SOLID SOLUTION

Considering the ferrite alone, two cases arise. First of all, there is the common one, in which the ferrite is present in contact with some carbide and acts as the anode in a galvanic couple.

This case is perfectly simple, the action coming about in consequence of the solution pressure of the iron (the

electro-affinity of iron—i.e., the potential of the metal against a normal ionic solution of its own ions—is—0.063 volt, iron being one of the metals which have a greater tendency to exist in the ionic than in the atomic condition). The negative electro-affinity in the case of the iron, and the positive (assumed) in the case of the carbide, produce all the essentials for galvanic action.

The other case is that of a relatively pure metal—e.g., bar iron—in which practically the whole of the material is composed of crystals of ferrite. As is well known, this material does corrode, and fairly rapidly too. The corrosion on the part of the ferrite in this case has been explained by the galvanic theory, on the assumption that the various grains of the metal have somewhat different solution pressures in consequence of the variation in the orientation of the different crystals. Also the presence of different degrees of mechanical strain in the various crystals is invoked as an explanation of this.

It appears possible, however, that neither of these explanations is necessary, in view of the more accurate knowledge that we possess of the structure of pure metals. Many workers have demonstrated the existence of a material in between the crystals of a metal, which has properties quite different from those of the adjacent crystals. The theories that have been advanced as to the nature of this material need not concern the present discussion, since they all have a point of agreement in that they admit the material to be amorphous.²

The orientation of the adjacent grains being different, there exists in this intergranular volume a material having the orientation of neither. It has been shown by various workers that the properties of an amorphous metal are very different from those of the same metal in the crystalline condition. Amongst other things, it has been made very probably true, that an amorphous substance is possessed of a very different solution pressure from that of the crystalline substance. It has been definitely established frequently, that a worked material has a much greater solution pressure than an unworked one;³ and as the amorphous layer in between the crystals has a relatively close similarity to a worked material, it is not unreasonable to imagine that the solution pressure of this layer is greater than that of the adjacent crystals. Lüttke⁴ has shown that mirror silver (which is in the strained or worked condition) will show a potential difference of as much as 0.1 volt when coupled with ordinary silver in dilute acids, and Andrews⁵ has found that the strained and unstrained portions of a wrought iron shaft gave a difference of potential of 0.016 volt, in a solution of sodium chloride.

Whichever phase has the greater solution pressure, the result of the existence of a potential difference will be galvanic action, and hence corrosion. This galvanic action would be between the intercrystalline material on the one hand, and the crystals of ferrite on the other. Either of these may be the positive member of the couple, and lose weight. In a perfectly annealed specimen, in which there is but little mechanical strain, it is probable that the action will be confined to that between the ferrite and the cement. If there is any potential difference, however, between the crystal grains due to any cause, then this will add to the effect, and the total corrosion will be the sum of the two actions. It is just possible, though improbable, that the solution pressure of the cement may lie midway between that of the more positive and the more negative grains of ferrite, in

TABLE I

Carbon, per Cent	Other Element, per Cent	LOSS OF WEIGHT IN		
		3 per Cent Sodium Chloride Solution	Tap-Water	10 per Cent Sulphuric Acid
0.50		0.992	0.88	4.57

which instance the action of the cement will be anodic in one case and cathodic in another.

Taking the simplest case, namely, the one in which the ferrite is roughly at the same potential throughout, and the intergranular cement at another, then there should be an action developed at the junction of the two substances. The action may not be confined to this face of contact, but will proceed at a maximum rate on that plane. The result should then be that the lines of junction of the crystal show this more intense action, and the evidence should take the form of a relatively deep pit sunk round the crystals. That this evidence is to hand may be seen from the photograph No. 3 (Plate 1), which shows a melted bar iron, having the following composition: carbon 0.07 per cent; silicon 0.018 per cent; manganese 0.09 per cent; sulphur 0.031 per cent; phosphorus 0.010 per cent, after undergoing corrosion in sodium chloride. This theory would account more or less completely for the corrosion of a pure metal.

Passing on to the question of solid solutions, several very interesting points arise at once. Assuming that the action in the case of steel containing carbide and solid solution is similar to that in those consisting of carbide and ferrite, that is, galvanic with the carbide as cathode, it should be evident that the controlling factor in this instance will be the solution pressure of the solid solution, and this will vary with its composition.

The solid solution found in steels have very various compositions, and these have been determined indirectly by Arnold and Read,⁴ and directly by the author.⁵

The results obtained are of interest, and show that in the case of molybdenum, vanadium and tungsten, these elements do not enter into the solid solution until a relatively high percentage of the element is present. At first the tungsten, vanadium and molybdenum are associated entirely with the carbon, and form a part of the carbide. In the case of vanadium, the "saturation" percentage of the carbide is about 5.4, for tungsten about 11.7, and for molybdenum about 19.0. Below these percentages these elements are not found in the solid solution. As a result, the concentration of the solid solution for these elements, even after they do find their way into this constituent, is never very high.

In the case of chromium, this element appears in both carbide and solid solution from the start, and hence the solid solution is much more concentrated in chromium at lower percentages than for any of the previous elements. Nickel behaves in a way just the opposite of vanadium and molybdenum. In the case of that element the carbide is found to be free from nickel until the steel contains more than 8 per cent of nickel. Prior to this the

solid solution receives all the nickel, and in consequence is more concentrated at lower percentages than that found in any of the other alloys.

Up to the present our knowledge of the actual electromotive force curves of these alloys of iron with vanadium, tungsten, molybdenum, etc., is not very great, but the general type of curve provided by a solid solution is well known. In general, it is a logarithmic curve of the form indicated in Fig. 1.

It will be granted that in all the alloys designed to resist corrosion, it will be necessary for the solution pressure (as reflected in the electromotive force) of the solid solution to undergo some considerable change from that of iron, in order that the difference of potential between the solid solution and the carbides shall be sufficiently small as to minimize corrosive action. From the electromotive-force curve it should be evident that there is no sudden change of solution pressure in the alloys forming the solid solution, and that in consequence it will be necessary for the solid solution to become relatively concentrated in the alloying element before the required change of solution pressure can be accomplished.

The corollary to this is surely that there is only likely to be any diminution of corrosion if the new element finds its way into the solid solution early in the series, and also becomes present in reasonable proportions. For any element that goes into solid solution in the steel a small percentage is not likely to be of the slightest value in resisting corrosion. That this view is true may be seen from the following cases.

The author has examined the influence of composition upon the corrosion of steels by determining the loss of weight experienced in various liquids by steels containing carbon only, and carbon with varying percentages of tungsten, vanadium, chromium, cobalt, molybdenum, copper, nickel and manganese.⁶ The results of these experiments show that very few steels containing a third element have any advantage to offer over those containing merely iron and carbon.

The most conspicuous exceptions are the steels containing a high percentage of chromium. The corrosion curve for these alloys is shown in Fig. 2, and it will be seen that it is only in those alloys where there is a good deal of chromium that any improvement occurs. As was stated above, in these steels the chromium is found in both the carbide and the solid solution; from the smallest percentages and the composition of the solid solutions for the steels whose corrosion was shown in Fig. 2 are given in Fig. 3. There it will be seen that the solid solution does contain a reasonably high per-

centage of chromium in those alloys which resist corrosive attacks.

Nickel steels are another series of materials which have a definite resistant action toward corrosive media, and in this case the conditions are very similar to those holding in the case of chromium. In these steels the

FIG. 2—CORROSION CURVE FOR CHROMIUM STEELS

nickel does not enter the carbide to any extent until more than 8 per cent is present, and hence there is produced a solid solution which contains a reasonably large percentage of this element. Thus in the two best-known examples of anti-corrosive steel the conditions demanded by theoretical consideration are fulfilled.

Yet another example may be put forward. In the steels containing cobalt there is found to be a fall of corrosion with an increase in the percentage of the cobalt. This is remarkable in one sense, because in the steels containing the higher percentages of cobalt the carbides had decomposed and precipitated graphite, a material calculated to cause a violent increase of corrosion if the solid solution has a suitable solution pressure. This increase of corrosion, however, does not take place, and this can only be due to the reluctance of the solid solution to act in an anodic manner. As the percentage of cobalt in the solid solution is found to be quite high, this is not surprising if the theory of the influence of electromotive force be allowed.

FIG. 3—SHOWING CHROMIUM PER CENT IN SOLID SOLUTION AGAINST CHROMIUM PER CENT IN STEEL

Another case is that of the vanadium steels. The curves for the corrosion of these steels are shown in Fig. 4, and it will be seen that there is an increase in the corrosion up to the steel containing 5.84 per cent of vanadium. After that the corrodibility decreases very appreciably. This is what might be expected in view of the composition of the solid solution. No vanadium is to be found in the solid solution up to the saturation point of the carbide, which is about 5.4 per cent of vanadium in the steel. At 5.84 per cent the solid solution is found to contain 1 per cent of vanadium, at 10.3 per cent it has 3.8 per cent and at 13.45 per cent as much as 7.2 per cent. Hence some distinct influence upon the electromotive force might be expected in consequence of the change of composition. If this change of solution pressure has resulted, then there will be a fall of corrosion, such as is actually found to happen.

FIG. 4—CORROSION CURVE FOR VANADIUM STEELS

In the other steels examined—*e.g.*, those containing molybdenum and tungsten—there is no resistance to corrosion to be found. The compositions of the solid solutions in these cases show that there is never a formation of anything approaching a concentrated solution. In the molybdenum steels, the one containing 20.7 per cent of molybdenum has a solid solution in which the percentage of molybdenum is about 2.2. In the tungsten steels there is no tungsten to be found in the solid solution up to about 12 per cent, and beyond that only a small proportion, since the tungsten associates itself with the carbide part as both a double carbide of iron and tungsten, and also as a tungstide of iron. As a result one would not expect that these steels—*i.e.*, containing molybdenum or tungsten—would have any great resistance to corrosion, and this is found to be the case. These experiments all appear to support the theory that the corrosion of a steel is determined mainly by the solution pressure of the solid solution which the steel contains.

The microstructure of these ferro-alloys are also a powerful support of this same theory. The idea has been held for a long time that non-homogeneity in a steel is the primary factor in producing corrosion. This may be correct within certain limits, and given a satisfactory definition of homogeneity, but it is generally assumed in consequence of this idea, that a steel possessed of a complex structure is bound to be corrosive.

This view can no longer be held in face of the structure of the chromium steels that resist corrosion so successfully. The structure of a non-corrosive chromium steel is shown in micrograph No. 4, and it may be seen at once that this steel is quite the reverse of homogeneous, being composed of a very intimate mixture of solid solution and carbide. Here the number of possible galvanic couples per square centimeter of exposed surface is enormous, and everything that could be an aid to corrosion is apparently present. Yet there is no corrosion in weakly attacking media. This can only be due to a lack of power to go into solution on the part of the solid solution—that is, to a negligibly small solution pressure with respect to these media.

Again, take the case of a material of conspicuous chemical homogeneity—the bar iron illustrated in photograph No. 3. Here there is corrosion to an appreciable extent, and this can only be due to a difference of solution pressure among the constituents of the material, as stated above.

A further example may be quoted, that of a solid solution in which twinning of the crystals is present. The microstructure revealed by corrosion in this case is illustrated in micrograph No. 5, and this steel corroded to a very considerable extent. In this case there could be no lack of chemical homogeneity, the only difference between the various parts of the crystals being one of orientation, which would be reflected by a variation of the solution pressure. Yet the mere fact of twinning does not necessarily produce a corrosive solid solution, for some of the nickel steels containing a considerable percentage of nickel have twinned crystals in abundance, but yet only corrode very slightly. Surely these facts support the theory that the solution pressure of the solid solution is the important factor in deciding the corrosion or non-corrosion of a steel.

Following upon the action first of carbides and then of solid solutions (including ferrite) comes the behavior of pearlite—the remaining constituent of steels. This component in the structure of steels is, of course, a mixture in definite proportions of ferrite (or solid solution) and a carbide (simple or complex). Two actions are possible with respect to this constituent—it may act either as a mixture or as a whole. Both these opinions have been held. Viewing the matter from the point of view of the solution pressure of the constituents, it is a little difficult to see how the pearlite can act as a separate simple constituent. The potential of a eutectic, or a mixture, is that of the constituent having the greater solution pressure (that is, the one showing the greater tendency to become ionic), and in the case of pearlite this undoubtedly is the ferrite. If, then, the pearlite be acting as a whole, it should corrode in accordance with the potential difference set up between itself and the neighboring component, which is the large areas of the ferrite. But if the pearlite be regarded as a whole, then the solution pressure of the pearlite and of the ferrite will be the same, or almost the same. Hence there should be no corrosion. Also, if there were corrosion, then there should be a preferential attack upon either the ferrite or upon the pearlite.

Taking the other view, that the pearlite acts not as a whole, but as a mixture of ferrite and carbide, then the corrosion proceeds in accordance with the usual potential difference set up between these two constituents. This will mean that in any particular grain containing, *e.g.*, ferrite and pearlite, the two components of the galvanic couple will be the carbide on the one hand, and the ferrite forming the body of the grain on the other. Hence, as the whole of the ferrite in the grain is part of the same electrical unit, whether it belongs to the pearlite or to the ferrite, the anodic action should take

place all over the ferritic surface exposed to the corrosive liquid. In this way the ferrite will dissolve all over the surface of the grain, and the carbide will be unattacked.

If a series of pearlitic steels of different carbon content be corroded, and then examined microscopically, it will be found that the resulting structures are almost indistinguishable one from the other. In no case, after an attack of about ten days, can the pearlite structure be observed, and, except for the attacks at the crystal boundaries present in a bar iron and absent in the steels, the pearlitic steels all present the appearance of a corroded iron. The carbide has disappeared, unless a fairly large piece is present when it is left standing in a field composed apparently of badly pitted and corroded ferrite. There is no trace of a separate area of attack of ferrite in pearlite, and it is not possible to distinguish between a steel containing 0.4 per cent of carbon, and one with 0.9 per cent. A typical structure is that shown in micrograph No. 6, a steel with 0.89 per cent of carbon, after corrosion. This can only mean that the ferrite is attacked throughout, whether in the free ferrite areas or in those of pearlite.

The carbides will not have been attacked, this having been proved by many experiments quoted above, and hence their disappearance from the steel can only be due to mechanical means. This, of course, is quite a probable explanation of the action which has taken place, the ferrite being attacked by the corrosive liquid and dissolved away. This removes the support which held the carbide in position, and allows it to fall out during the washing which must necessarily precede microscopic examination after corrosion. The presence of the loose carbide on the surface of a corroded sample that has not been disturbed is usually fairly obvious. If the carbide is massive, it is like to be rooted more deeply in the mass, and hence on light corrosion is not removed.

This accounts for the structure of the steel shown in microphotograph 1, in which the carbide of the crystal boundaries (the cementite) remains clear and unattacked, while that of the pearlite, which normally occupies the body of the crystal, has disappeared. In some of the alloy steels which contained pearlite, and were examined, the corrosive action had not gone far enough to remove all the carbide of the pearlite from its matrix, and traces of the pearlite structure might be still seen in the resulting microsection.

The conclusions to be drawn from the above may be summarized as follows:

- (1) That the corrosion of a steel takes place purely by the action of the ferrite or the solid solution.

- (2) That the action upon pure ferrite may be due entirely to the potential difference set up in consequence of the different solution pressures of the grains of the metal and the inter-granular cement, it being probable that this latter is possessed of a greater electromotive force.

- (3) That the percentage of the third element added to iron and carbon in steels must be sufficiently great to produce a fairly high percentage in the solid solution, if there is to be any beneficial effect from the use of this element.

- (4) That the electromotive force of the solid solution with respect to the corrosive liquid is the deciding factor in the corrosion of a steel.

- (5) That the pearlite in a steel does not corrode as a whole, but as a mixture of ferrite and cementite, the disappearance of the latter being due to mechanical, and not to chemical action.

- (6) That carbides are not decomposed by ordinary corrosive agents, and that they act merely as cathodes to the anode of the ferrite or solid solution.

Concentration and Flotation of Lead Ores in Southeast Missouri

(Editorial Correspondence)

General

The region of disseminated lead ores in Southeast Missouri is the oldest of the large lead-producing districts in the United States. Production from ores in the lower Bonne Terre dolomite is recorded as early as 1869, though earlier production was made from shallow surface pockets. The principal towns of the district are Bonne Terre, Desloge, St. Francois and Flat River, and the producing area is included within a radius of five miles from the vicinity of Desloge-St. Francois. The operating companies are the Federal Lead Co., St. Louis Smelting & Refining Co., Desloge Consolidated Lead Co., and the St. Joseph Lead Co., which also controls the Doe Run Lead Co. To the managers and technical staffs of these companies we are indebted for many courtesies extended and for information on recent concentrating practice in the district.

Six concentrating mills are operated by the four concerns named. A seventh will be in operation this Fall when the new 2500-ton mill of the Federal Lead Co. will be completed. Further addition to the gross mill capacity of the district will result from changes in flow-sheet and equipment at the St. Louis company's mill which will treat 4000 tons per day. The various mills and their approximate daily capacities are listed below.

Name of Company	Mill Capacity Tons in 24 Hr.
Federal Lead Company	5,000
St. Joseph Lead Company, Bonne Terre	2,100
St. Joseph Lead Company, Leadwood	1,300
St. Joseph Lead Company, Rivermines	4,200
St. Louis Smelting & Refining Company	2,500
Desloge Consolidated Lead Company	1,800
Total	17,500

Similarity in the nature and occurrence of the ore on the different properties gives rise to practical uniformity in the methods of concentration, so that except for a few minor variations the milling methods bear a close resemblance to each other. This is true not only of past practice but also in the changes and improvements that are being introduced. The district being comparatively small and compact and the conditions reasonably uniform, the problems of the several companies are similar, varying mainly in degree. This accounts for the general use of the Hancock jig, the gradual adoption of the Butchart table or system of riffing, and the similarity in flotation equipment and practice at all mills.

Crushing and Grinding

The mills are usually erected adjacent to working shafts and the coarse-breaking plant is housed in the mill structure. In other cases run-of-mine ore is crushed at isolated shafts and the crushed ore transported to the mills. Gyratory crushers in large and medium sizes find favor for primary and secondary crushing and are generally adopted. The well known advantages of this type of breaker in handling a large tonnage of ore that is not too wet and sticky, with favorable power consumption and labor attendance, make it a desirable machine where run-of-mine does not come in too large pieces.

A departure from the general use of gyratories, however, is being made at the new coarse-crushing plant of the St. Louis mill, where a Traylor jaw breaker, 30 in. by 60 in., is being installed. The St. Louis mill was built in 1900 to treat 1200 tons of ore per day, but is now handling 2500 tons, with a prospect of 4000 tons when certain changes are made. The weak point in the

system, even at the lower tonnage, was the gyratory equipment which had insufficient capacity on run-of-mine ore, since many of the rocks were too large to be nipped. Capacity could have been increased with the present equipment by screening out the fine, but even then the large pieces would give trouble. It became practically necessary, therefore, either to build a new crushing plant with coarse breakers large enough to handle the big rocks, or remove the fine by screening and crush the oversize to say 4 in. or 5 in. for the present gyratories. A large gyratory could have been used, but in order to handle the large size feed its capacity would have to be unnecessarily great. Consequently the jaw crusher was adopted for primary work, since it would take larger size rock than a gyratory, considering equal capacities for the two machines, and also permit the continued use of the present crushing plant. The large opening of the jaw crusher was the decisive factor in its selection.

At the Federal mill gyratories are used as primary crushers to about 3½ in. and are followed by Symons 48-in. disc crushers giving a ¾-in. product. Similar equipment will be used at the same company's new mill. Where run-of-mine comes unusually large, a good sequence of crushing machines would be jaw breaker, gyratory, disc crusher and rolls.

Rolls are generally used for fine crushing and re-grinding, and at two of the mills, the Bonne Terre which is the oldest in the district, and the Desloge, the old Cornish geared rolls are still in use. The first introduction of the modern ball-mill for re-grinding is being made at the Rivermines mill of the St. Joseph company, where an 8-ft. diameter Marcy mill operated by a 200-hp. motor is being placed. This machine will be used for re-grinding certain screen oversizes and jig middlings and will be substituted for rolls. The installation is of an experimental nature to determine the efficiency and economy of the modern mill, and its further use will depend on the results obtained from its operation.

Screen-Sizing and Jigging

Screen-sizing is not done on as elaborate a scale as it was before the Hancock jig displaced the Harz, and only one product is now prepared, the limiting sizes being generally 9 and 2 mm. Two types of screens are in use for this work—trommels for both coarse and fine separation, and flat shaking screens, the latter being used in some mills for 2-mm. separation. Most of the trommels are cylindrical, but a few of hexagonal form with horizontal shafts are still in use at one mill for fine work. The tendency, however, to adopt the flat shaking screen of the Ferraris type in place of trommels for screening fine sizes, is in line with the claims of some authorities for the advantages of flat screens. The elimination of undersize grains is more readily accomplished due to lack of interference in their progress across the screen; and more frequent opportunities are afforded the particles to pass through the apertures by reason of frequent changes of position during their travel.

At one of the mills jig feed is prepared by drag classifiers which receive the undersize of 9-mm. trommels. In this case the fine material from the drag is prepared for table and flotation treatment.

As stated before, the Hancock jig is used in all the mills, having entirely displaced the Harz type. Its advantages are well known, but may be briefly reviewed. It will be apparent from the remarks on screening that jigging is done without close sizing, the limits being 9 and 2 mm. The ability of the Hancock jig to effect a separation of mineral according to specific gravity,

practically regardless of size, has made it possible to dispense with the long trains of trommels which formerly were necessary to size the feed for Harz jigs. Further, the Hancock requires less floor space than a number of Harz jigs of equal capacity; it uses very much less water and consumes less power.

The grade of jig feed will range from 3 per cent to 5 per cent lead, and the tailing will run about 0.7 per cent. The escape of fine mineral in the tailing formerly involved a loss which is now obviated by the flotation process. Jig tailings are dewatered either by means of a wheel scoop or by discharging over a screen, and the slimy water is added to other slime pulps and thickened for flotation.

Changes in Table Concentration

In table concentration the two most notable tendencies throughout the district are the abandonment of close classification and the general adoption of the Butchart system of riffling.¹

In table feed the particles range in size from 2 mm. downward, being the undersize of a 2-mm. screen or the overflow of a drag classifier. Formerly this pulp was hydraulically classified into a number of products for sand and slime table treatment, but the present practice consists in desliming the minus 2-mm. pulp, making separation at a point as near 150-mesh as possible. The portion minus 2-mm. and plus 150-mesh is then distributed to sand tables without further classification and the minus 150-mesh grade is in some cases distributed to slime tables or directly thickened for flotation.

Among the desliming devices, which are of local design, may be mentioned the Delano, which is in process of patenting by L. A. Delano, superintendent of the Bonne Terre mill of the St. Joseph Company. Designed to make a separation at 150-mesh, this device has shown high efficiency in practice, yielding 96 per cent minus 150-mesh in the overflow and 93 per cent plus 150-mesh in the underflow.

With the Butchart system of riffling, hydraulic classification other than desliming is unnecessary. The point at which the slime separation is made must be determined for each ore; but once determined, an unclassified feed is tabled successfully. The capacity of a table under the new system of riffling is greatly increased over the old, and water requirement is much less. At the Bonne Terre mill eighteen tables re-riffled according to the new system are treating a slightly larger tonnage than was formerly handled on fifty-two tables with other riffling, showing an increase in capacity of about three times. At the same mill, also, all jig and table concentrates are combined and re-treated over tables with Butchart riffles. The combined concentrates are separated at about 150-mesh into fine and coarse grades by a Delano deslimer, and re-treated over separate tables. The fine yields a product containing 80 per cent lead, and 75 per cent of the concentrate is finer than 200-mesh. The net effect of this re-treatment is to raise the grade of shipped concentrate from 62 per cent lead to from 75 per cent to 77 per cent.

Another factor in the success of the new system of riffling is the means for rapidly separating the stratified mineral without overloading a cleaning zone. It is also reported that large variations in the rate of feed can be tolerated, up to 10 tons per day, without requiring adjustment of the table.

A notable effect of the changes in classification and table treatment is the reduction in quantity of mill water used. Where the changes have not yet been

made, and the old systems still prevail, it is observed that the slime thickening equipment ahead of flotation is overburdened with an excess of water.

General Practice of Flotation

Flotation is practised at all the mills in the Lead Belt, and as might be expected in a district where conditions at the several mills are similar, the methods employed and results obtained are quite uniform. The average tonnage treated by flotation is from 12 per cent to 15 per cent of the ore milled, or between 2000 and 2500 tons per day. Some of this tonnage represents a former waste, and part of it was concentrated on vanners or canvas plants, which have since been abandoned.

It is customary to collect all slime pulps from jig and table tailings, classifier overflows, etc., and combine them into a flow to Dorr thickeners, where flotation feed is prepared. No acid or heat is employed at any of the mills, nor are chemical addition agents of any kind necessary. The water used in milling is pumped from the mines, and owing to the limestone and dolomite formations from which it comes it is very hard. The same oil is used at all mills, known as No. 2 creosote, prepared by the oil department of the Cleveland-Cliffs Iron Company. This is probably a mixture of wood creasote and other oils, and is used as received. The cost is about 14 cents per gallon, and consumption varies from 0.5 to 0.75 lb. per ton of feed.

Three types of flotation machines are in use: Minerals Separation and Janney agitation machines, and air cells like the Callow. The first two types are used for the main treatment, and their tailings are re-treated in air cells without further addition of oil. The only instance of recleaning flotation concentrate is at the Federal mill, where the froth from an air cell is re-treated in a single-cell Janney machine.

Most of the agitation machines are composed of sixteen cells, all provided with settling and flotation compartments. An exception to this general rule is the twenty-four-cell Minerals Separation machine at the St. Louis mill, two cells of which are used for mixing and agitation only, with twenty-two yielding a froth. With one or two exceptions all machines are belt-driven and require from 4 to 4½ hp. per cell. It is customary to use small pumps to deliver the oil to the machines, adding it at every second or third cell.

The grade of flotation feed will range from 2.5 per cent to 3 per cent lead. Concentrates from agitation machines contain from 65 per cent to 45 per cent lead, ranging downward from the first compartment to the last. The product of the air cells which re-treat tailings from the agitation machines is lower in grade, running from 20 per cent to 40 per cent lead, according to the material treated. Final tailing contains from 0.2 per cent to 0.5 per cent lead. All flotation concentrates are combined into one product, not only from the individual cells of the agitation machines, but also from the latter and the air cells. This gives a final product containing from 47 per cent to 52 per cent lead.

In the operation of the air cells a steady supply of air at from 5 to 7 lb. pressure, delivered by a blower specially provided for the purpose, has been found essential to good work. Where blowers have not been installed air is taken from the high-pressure air line through a pressure-reducing valve, but the result is not as satisfactory as with air from a low-pressure blower. The latter gives a steadier supply than the other method, and makes the work of the cell more uniform.

Handling Flotation Concentrate

The dewatering of concentrates is accomplished by first thickening in Dorr thickeners. At some of the

2881, 2882, 2883, 2884, 2885, 2886, 2887, 2888, 2889, 2890, 2891, 2892, 2893, 2894, 2895, 2896, 2897, 2898, 2899, 2900, 2901, 2902, 2903, 2904, 2905, 2906, 2907, 2908, 2909, 2910, 2911, 2912, 2913, 2914, 2915, 2916, 2917, 2918, 2919, 2920, 2921, 2922, 2923, 2924, 2925, 2926, 2927, 2928, 2929, 2930, 2931, 2932, 2933, 2934, 2935, 2936, 2937, 2938, 2939, 2940, 2941, 2942, 2943, 2944, 2945, 2946, 2947, 2948, 2949, 2950, 2951, 2952, 2953, 2954, 2955, 2956, 2957, 2958, 2959, 2960, 2961, 2962, 2963, 2964, 2965, 2966, 2967, 2968, 2969, 2970, 2971, 2972, 2973, 2974, 2975, 2976, 2977, 2978, 2979, 2980, 2981, 2982, 2983, 2984, 2985, 2986, 2987, 2988, 2989, 2990, 2991, 2992, 2993, 2994, 2995, 2996, 2997, 2998, 2999, 3000, 3001, 3002, 3003, 3004, 3005, 3006, 3007, 3008, 3009, 3010, 3011, 3012, 3013, 3014, 3015, 3016, 3017, 3018, 3019, 3020, 3021, 3022, 3023, 3024, 3025, 3026, 3027, 3028, 3029, 3030, 3031, 3032, 3033, 3034, 3035, 3036, 3037, 3038, 3039, 3040, 3041, 3042, 3043, 3044, 3045, 3046, 3047, 3048, 3049, 3050, 3051, 3052, 3053, 3054, 3055, 3056, 3057, 3058, 3059, 3060, 3061, 3062, 3063, 3064, 3065, 3066, 3067, 3068, 3069, 3070, 3071, 3072, 3073, 3074, 3075, 3076, 3077, 3078, 3079, 3080, 3081, 3082, 3083, 3084, 3085, 3086, 3087, 3088, 3089, 3090, 3091, 3092, 3093, 3094, 3095, 3096, 3097, 3098, 3099, 3100, 3101, 3102, 3103, 3104, 3105, 3106, 3107, 3108, 3109, 3110, 3111, 3112, 3113, 3114, 3115, 3116, 3117, 3118, 3119, 3120, 3121, 3122, 3123, 3124, 3125, 3126, 3127, 3128, 3129, 3130, 3131, 3132, 3133, 3134, 3135, 3136, 3137, 3138, 3139, 3140, 3141, 3142, 3143, 3144, 3145, 3146, 3147, 3148, 3149, 3150, 3151, 3152, 3153, 3154, 3155, 3156, 3157, 3158, 3159, 3160, 3161, 3162, 3163, 3164, 3165, 3166, 3167, 3168, 3169, 3170, 3171, 3172, 3173, 3174, 3175, 3176, 3177, 3178, 3179, 3180, 3181, 3182, 3183, 3184, 3185, 3186, 3187, 3188, 3189, 3190, 3191, 3192, 3193, 3194, 3195, 3196, 3197, 3198, 3199, 3200, 3201, 3202, 3203, 3204, 3205, 3206, 3207, 3208, 3209, 3210, 3211, 3212, 3213, 3214, 3215, 3216, 3217, 3218, 3219, 3220, 3221, 3222, 3223, 3224, 3225, 3226, 3227, 3228, 3229, 3230, 3231, 3232, 3233, 3234, 3235, 3236, 3237, 3238, 3239, 3240, 3241, 3242, 3243, 3244, 3245, 3246, 3247, 3248, 3249, 3250, 3251, 3252, 3253, 3254, 3255, 3256, 3257, 3258, 3259, 3260, 3261, 3262, 3263, 3264, 3265, 3266, 3267, 3268, 3269, 3270, 3271, 3272, 3273, 3274, 3275, 3276, 3277, 3278, 3279, 3280, 3281, 3282, 3283, 3284, 3285, 3286, 3287, 3288, 3289, 3290, 3291, 3292, 3293, 3294, 3295, 3296, 3297, 3298, 3299, 3300, 3301, 3302, 3303, 3304, 3305, 3306, 3307, 3308, 3309, 3310, 3311, 3312, 3313, 3314, 3315, 3316, 3317, 3318, 3319, 3320, 3321, 3322, 3323, 3324, 3325, 3326, 3327, 3328, 3329, 3330, 3331, 3332, 3333, 3334, 3335, 3336, 3337, 3338, 3339, 3340, 3341, 3342, 3343, 3344, 3345, 3346, 3347, 3348, 3349, 3350, 3351, 3352, 3353, 3354, 3355, 3356, 3357, 3358, 3359, 3360, 3361, 3362, 3363, 3364, 3365, 3366, 3367, 3368, 3369, 3370, 3371, 3372, 3373, 3374, 3375, 3376, 3377, 3378, 3379, 3380, 3381, 3382, 3383, 3384, 3385, 3386, 3387, 3388, 3389, 3390, 3391, 3392, 3393, 3394, 3395, 3396, 3397, 3398, 3399, 3400, 3401, 3402, 3403, 3404, 3405, 3406, 3407, 3408, 3409, 3410, 3411, 3412, 3413, 3414, 3415, 3416, 3417, 3418, 3419, 3420, 3421, 3422, 3423, 3424, 3425, 3426, 3427, 3428, 3429, 3430, 3431, 3432, 3433, 3434, 3435, 3436, 3437, 3438, 3439, 3440, 3441, 3442, 3443, 3444, 3445, 3446, 3447, 3448, 3449, 3450, 3451, 3452, 3453, 3454, 3455, 3456, 3457, 3458, 3459, 3460, 3461, 3462, 3463, 3464, 3465, 3466, 3467, 3468, 3469, 3470, 3471, 3472, 3473, 3474, 3475, 3476, 3477, 3478, 3479, 3480, 3481, 3482, 3483, 3484, 3485, 3486, 3487, 3488, 3489, 3490, 3491, 3492, 3493, 3494, 3495, 3496, 3497, 3498, 3499, 3500, 3501, 3502, 3503, 3504, 3505, 3506, 3507, 3508, 3509, 3510, 3511, 3512, 3513, 3514, 3515, 3516, 3517, 3518, 3519, 3520, 3521, 3522, 3523, 3524, 3525, 3526, 3527, 3528, 3529, 3530, 3531, 3532, 3533, 3534, 3535, 3536, 3537, 3538, 3539, 3540, 3541, 3542, 3543, 3544, 3545, 3546, 3547, 3548, 3549, 3550, 3551, 3552, 3553, 3554, 3555, 3556, 3557, 3558, 3559, 3560, 3561,

mills an Oliver filter is used to further dewater the Dorr product, while at others the Dorr discharge is dried in shallow wooden tanks with steam coils in the bottom. The latter expedient is resorted to even if the filter is used, since it has been impossible to obtain a filter cake with less than 14 per cent moisture, whereas the smelters set a limit of not more than 7 per cent. Steam drying, therefore, appears at the present time to be a necessity in this district.

The general effect of flotation has been to increase the saving of lead, simplify the flow-sheet of the mills, and in some cases, to eliminate canvas tables, vanners or other tables for concentrating slime. Reciprocating tables are still in use in some mills for slime concentration, and in such cases the tailings from these tables are floated. The re-treatment of old slime tailing dumps is another development made possible by flotation. At the Rivermines mill an old slime pond is being reclaimed by hydraulicking and pumping to Dorr thickeners, where the pulp is combined with current slime tailings. The hydraulic water lines and pumps are operated from rafts on which the machinery is housed, the rafts floating in natural sumps in the pond to which the slime pulp gravitates as it is dislodged from the surrounding banks by the hydraulic streams. Pumps are belt-driven from motors, and flexible connections are made between the pumps and permanent pipe lines along the edge of the pond.

The consistency of flotation feed varies somewhat at the different mills, but in general is three parts water to one of solids. At the St. Louis mill the ratio is 6:1, which is the thinnest pulp treated. It is at this plant also that the twenty-four-cell machine is used, and while an oil consumption slightly higher than the average is admitted, a lower tailing, 0.2 per cent lead, is claimed.

The foregoing memoranda on flotation are general for the district. More detail of operation can be given on the work of the St. Joseph company at the Bonne Terre mill, where no other form of slime concentration is practised.

Flotation at the Bonne Terre Mill

The overflow from the Delano deslimers, together with other waste slimes from concentrating machines, representing about 15 per cent of the daily mill feed of 2100 tons, is thickened in five Dorr thickeners, four of which are 40 ft. by 8 ft. and one 44 ft. by 6 ft. They run at the rate of one revolution in ten minutes, and the discharged pulp has a water:solids ratio of $3\frac{1}{2}$ or 3:1. A screen test of the discharged solids will show from 95 per cent to 97 per cent finer than 150-mesh and from 88 per cent to 90 per cent finer than 200-mesh.

The thickened pulp flows to a sixteen-cell Minerals Separation machine, the impellers of which run at 300 r.p.m. The power requirement is 72 hp. Oil is added at every other agitation compartment, beginning with the first. Formerly the entire quantity of oil was added at the first agitator but experience showed that subsequent additions were necessary before treatment was complete, so the practice was adopted of distributing the oil to successive compartments as needed to make a good recovery. A slight difference is noted in the results obtained in winter and summer, the latter showing an improvement, but the difference is not sufficient to warrant the expense of heating the pulp. The consumption of oil is 0.7 lb. per ton of feed.

Froths from all cells are combined into one product, even though the grade of concentrate from the head compartments is higher than that from the other end of the machine. These products will range, respectively, from 65 per cent to 50 per cent lead. The tailing is elevated by centrifugal pump to an air cell for final treatment, and a concentrate containing from 30 per cent to

40 per cent lead is obtained and combined with the froth from the agitation machine. The average grade of the mixture is 52 per cent lead, and final tailing contains from 0.35 per cent to 0.5 per cent lead. Air is supplied to the final machine at 7 lb. pressure.

The flotation concentrate flows to a belt and bucket elevator, which raises it to a Dorr thickener, 38 ft. by 6 ft., running at the slow rate of one revolution in thirty minutes. Thickener feed contains 90 per cent moisture and discharge 40 per cent. Other means were tried for raising the pulp to the thickener, but the elevator was found best since it aided in breaking the froth when the buckets discharged their load. Pumps aggravated the frothy condition of the pulp and had to be abandoned. The froth is very persistent, and every means must be utilized to break it or avoid increasing it. Thus a spray of clean water is used over the receiving well of the thickener, and the incoming pulp is discharged above the surface, as this was found preferable to a submerged discharge. The use of oily water in the spray cannot be tolerated. Even with all precautions the accumulation of considerable dense froth on the surface of the thickener cannot be prevented, and from time to time it is removed by a hoe and again delivered to the elevator.

Filtration of Flotation Concentrate

The thickened pulp with 40 per cent moisture is further dewatered on an Oliver filter, which yields a cake $\frac{1}{8}$ to $\frac{3}{16}$ in. thick containing from 14 per cent to 15 per cent moisture. Persistent efforts and experiments have failed to lower the moisture in the filter cake below this point. On one occasion the entire filter was housed in a tight covering, and dry air at a temperature of 175 deg. Fahr. was blown into the inclosure in the hope of reducing the moisture content of the cake. The result was almost negative, for the moisture was not lowered appreciably below that obtained under normal conditions of operation. Heating the pulp with live steam also was tried, and while this did not effect a decrease in the moisture content of the cake, it had the unexpected and desirable effect of almost doubling the capacity of the filter, which up to that time was scarcely equal to the service demanded.

Since the smelters set a limit of 7 per cent moisture in concentrates, it is necessary to dry the filter product, as already explained, in tanks with steam coils in the bottom. As these tanks must be filled and emptied by hand, additional expense and delay in marketing are entailed by the process.

Oliver filters are in use at several of the mills and are being installed at others. The filter is a desirable machine, even if it cannot deliver a commercially dry product from this particular type of mineral slime, most of which is finer than 200-mesh. The drying of a 40 per cent moisture pulp in steam boxes is an expensive process, besides being slow, requiring additional labor and holding a large amount of concentrate in the process. The intermediate step of filtering to reduce moisture by 25 per cent, or 62.5 per cent of the total, must be more economical than attempting to remove the entire amount by heating.

Asphalt Industry in 1915.—According to the Geological Survey the asphalt industry enjoyed a prosperous year in 1915. Natural asphalt produced amounted to 75,751 short tons, valued at \$526,490, which was 5 per cent less than in 1914. The manufactured asphalt, however, made from domestic petroleum residues was 664,503 short tons, valued at \$4,715,583, or a gain of 84 per cent over 1914. There was also 388,318 short tons made from petroleum imported from Mexico.

Cost Accounting in the Construction and Operation of a Copper Smelter—IV

BY ERNEST EDGAR THUM, E. M.

Assistant Professor of Metallurgy, University of Cincinnati; Formerly, Engineer in Charge of Construction, Anaconda Copper Mining Company.

In previous instalments* of this series methods have been presented at considerable length for gathering information necessary for an adequate compilation of costs and accounts covering the construction and operation of a copper smelter. Lists of accounts into which it is necessary to segregate the expenditures have also been given. The discussion so far has been primarily devoted to subjects connected with accounts covering the money-cost of construction, repairs and reconstruction of the various mechanical and structural units comprising the complicated machine known as a modern copper smelter, e.g., buildings, furnaces, tracks and flues. Therefore, the more extensive subject of accounting for operating expenses has been mentioned only in passing; a list of useful operating accounts coordinating with the construction and repair accounts has been given, and it has been indicated how the account books, machinery and personnel of the construction cost-keeping bureau can be utilized by the operating departments.

It should again be emphasized that all time-cards, warehouse and shop orders should bear tersely worded descriptions of the particular detail of the job to which they refer, in addition to the appropriate account and sub-number. Only in this manner can the demands of both the cost-keeper and the auditor be fulfilled. The auditor could tell the manager the total cost of operating the blast-furnaces for any fiscal period, but the aid of the cost-keeper and metallurgist is required to discover the cost per ton of smelting rabble cleanings from the McDougall furnaces. Even their best efforts will be totally unavailing to produce important details of cost if the necessary information has not been gathered and noted on the spot and properly filed for future reference.

Progress in the metallurgical art results largely from an improvement of the details of a process rather than from a revolutionary change in the method itself, and in nearly all cases a revision of detailed practice is a success or failure in exactly the same measure as it decreases or increases the cost of the operation. How, then, can the manager be enabled properly to judge whether or not a variation in the routine would be desirable, if he is in ignorance of the cost of the old practice, and cannot discover the expense of the new?

Distribution of "Non-Productive" and General-Commodity Costs

The necessity for clear and adequate notations on all operating charges is particularly evident in such "non-productive" units as the power house department, which, as has been previously noted in the listing of operating accounts, cannot usually be adequately subdivided in the ordinary accounting system. The word "non-productive" is somewhat a misnomer, as the power house produces such valuable commodities as power, light, heat and blast. It is commonly used in accountant's parlance inasmuch as such departments are outside the continuous chain of smelting operations between ore and ingot; serving all, as need arises. The cost of operating the power house, therefore, becomes an "expense" to be absorbed by the "productive" departments.

The problem of determining the correct value and

proper estimation of the consumption of such widely used commodities is one of the most difficult for the management to solve, and becomes a mere matter of guesswork in many instances. However, if the proper care and attention has been bestowed upon the detailed labor and material charges day by day, the cost-clerks will be able to divide the sum total of the bookkeeper's account into parts representing the cost of producing high-pressure water, converter air, steam for heating and the dozen other kinds of power developed. Assuming that the plant is equipped with adequate meters, the reports of the power-house timekeeper will show the amount of each class of power "at the switchboard," whereupon the cost per horsepower, kilowatt, gallon or cubic foot can be immediately established. As demonstrated previously, these prices should evidently be fixed for a certain fiscal period and revised only at such long intervals (as experience with the profit-and-loss account will direct), in order to enable one to make rational comparisons of smelting costs, should they carry power charges.

Given the necessary data, then, the procedure will so far be comparatively simple, but the cost-keeper would seem to be in ignorance of what becomes of the power when it leaves the power house. Bear in mind, however, that time-cards for all large machines will be found on file giving a continuous history of their operations, as well as daily reports to the power-house clerk covering the operations of small tools and isolated equipment. Taking a concrete illustration, the amount of air consumed per hour per converter and its cost will be readily determinable—converter air is generated in a particular type of engine and is piped directly to the converters and used by them alone. But the electric power necessary for tilting is not so easy to fix—the driving motors are on a general power circuit supplying a 100-hp. motor at each converter operating 1 per cent of its time at 50 per cent overload, cranes with 300 hp. in motors operating 60 per cent of the time at 20 per cent capacity, motors for casting machines, ventilators, elevators, and so on, each operating under different conditions and load factors.

The total electricity furnished this circuit might have been metered at the substation, but the final destination will be at first a matter for the chief engineer's or master mechanic's best judgment. No time should be lost after operations are running along smoothly to check up and revise such estimates by a painstaking determination of the actual average power consumption of all machines, furnaces and departments. If properly made, the quantities so determined can be maintained as a fixed charge per hour on the time-card of every machine, and the sum total of all such for the month should balance within limits with the total output of the power-house. Any large discrepancy will be a signal for an investigation; the error will be corrected, or the leak quickly stopped. The time of a well-trained engineer could not be better invested than in continually watching the power distribution throughout a large smelter. The prime object of his labors would not be the construction of a nice power balance-sheet, but the detection and elimination of leaks; one large one discovered and corrected will save his salary for an indefinite period. Under his care it would be unnecessary to compress 800 cu. ft. of blast for every 100 blown through the tuyeres of the blast furnace, a condition reported by a recent metallurgical text.

All commodities used in the concentrating, smelting and refining processes should be as carefully watched and accounted for as the power accounts alluded to above. Water, for instance, costing thousands of dollars to develop, store, pump and deliver should not be

*Published in Vol. XIV, No. 1, p. 69, and Vol. XV, No. 1, p. 134.

turned loose at the rate of 50,000,000 gal. a day to the tender mercies of table and jig, sluice and cooling jacket without at least knowing how much of it each machine needs, and then seeing to it that one machine operative does not extravagantly waste another's portion. Such knowledge and supervision is the first step toward efficiency because it will lead naturally and quickly into comparative tests of alternative types of apparatus with the development of new schemes for saving money by the conservation of even such an ordinary commodity as water.

Special Attention Required for Gathering Information

The usual method in vogue in smelters of requiring straw-bosses to make out the time-cards would be entirely inadequate for the prosecution of the system here outlined. Owing to a press of more important duties connected with "getting the copper" he will fill in his reports and make up the time-cards in the hasty manner—shortly falling into the habit of jotting down merely the account number and sub-letter, failing even to properly distribute the time in case his men are working on more than one subdivision. Time-keeping and clerical work should not be expected of a foreman any more than responsible supervision should be asked of a clerk.

The method outlined for gathering information during construction should therefore be followed after the plant has been blown in; and, in general, it would be a wise policy to retain as many of the trained construction staff as will be necessary to handle the simpler and much more steady routine of operation.

The timekeeper assigned to each department should make a tour early in the shift, gathering the time-cards from the straw-bosses, noting at the proper place in his loose-leaf note-book the detailed information necessary to adequately describe the kind of work each man is doing and all unusual conditions which may surround the work. From the shift-boss and sampler he notes the number and time of machines, furnaces, converters or other large machines in operation; he makes a rough estimate of the amount of raw material (such as ore) in the bins and finished material (such as concentrates) ready for delivery, visits various indicating meters and makes periodical notations of their readings and changes and preserves charts on recording meters.

Such tours for inspection and information are repeated at intervals of two hours exactly as outlined previously in this discussion. During the day the timekeeper visits the warehouse and shops to examine the charges on current orders and makes out the time-cards for workmen and machines, in general, carrying out the routine learned during construction.

One of the duties to be performed early in the shift is to make a statement of conditions in the department at the beginning of the shift, appending necessary explanatory remarks, which is inspected carefully and initiated by the department foreman before being forwarded to the general foreman's office. The statements from all departments are here collated and condensed into a general tabulation of operating conditions for the information of the management. This general statement also bears information as to the amount of major supplies consumed and principal products produced, gleaned from reports of the transportation, unloading and tramming departments and of various scalemen placed at proper parts of the plant. Such a summary statement of operations, shorn of numerous minor details, is given in Table I.

Accounting of Metal in Process

A consideration of our dictum that all commodities

used in the concentrating and smelting process should be carefully watched and accounted for, leads us naturally to the thought that an accounting of the actual metal in process should show strikingly valuable information as to the operations in general, and the efficiency of small units in particular. This is entirely beside the idea held in some large organizations that each department should operate as a separate business concern, paying for what it uses and selling what it produces; and above all, operating at a profit. Evidently, under such a system, a knowledge of the metal consumption and production of the department as a whole is absolutely essential. The routine for the production of such information will now be outlined.

The concentrating department stands at the head of those necessary to turn ore into metal. Its receipts are low-grade ore from various mines and localities. The quantity of this ore is had from the transportation and unloading department reports showing the weight, point of origin and point of unloading of each carload or parcel of material. The consumption of these receipts is determined roughly by the daily receipts, less the estimates of the timekeepers of the amount of this material in the bins, and is adjusted monthly to accord with the careful inventory estimates made by the engineering staff of all quantities of ore in the concentrator bins, storage bins, stock piles, bedding system and any other place where material is held preliminary to treatment. The quality of the ore is a matter for the sampler and the chemist to determine. In case the ore comes from the company's own mines, the sampling and assaying is usually done at the point of origin. Foreign and custom ores are to be sampled in the ap-

proved manner. A discussion of the various arrangements of automatic machinery for such large quantities of material is beside the scope of this paper, for it has been excellently handled elsewhere by expert engineers who have given this particular branch of concentration their whole time and attention.

The metal accountant is enabled by a judicious use of this information at his disposal (i.e., inventory, receipts and analyses) to compute the consumption of the concentrator of copper, gold, silver, sulphur, iron, silica, alumina, lime, zinc, lead and any other substance which is a benefit or a detriment to the subsequent operations and which must, therefore, be either converted or eliminated to the fullest possible extent.

The production of the concentrator falls into four main classes, to wit, coarse concentrates, fine concentrates, slimes and tailings, each of which may possibly be differentiated as to the section of the mill which produced them, size, value or other characteristic. Leaving such variations out of account, the specific case of the disposition of coarse concentrates will best describe the general method of accounting for the production.

Specific Case of Coarse Concentrates

The coarse concentrates are laundered directly to the storage bins and sampled en route by automatic machines diverting the whole stream at regular intervals for a small period of time into a small tank placed nearby. This sample is collected by the sampling department, drained, weighed, dried, further cut down, ground and prepared for analysis in an approved manner. The analysis by the laboratory is forwarded to the metallurgist and the concentrator foreman, together with information as to the point of origin of the sample and the shift which produced it, and is scrutinized by them in the light of past performances and the ideal in mind to be attained.

The quantity of coarse concentrates is derived from the scaleman's reports, who records the weight, point of origin and destination of each carload drawn from these bins. The total of these weights should check with the amount of concentrates produced as derived from the weight of the sample obtained per shift; which, being gathered by automatic machinery, will represent a certain percentage of the amount of solid matter passing the sampler during its operation. At monthly intervals the engineers will make careful estimates of the quantity of concentrates on hand in each bin; these inventories, the scale weights of material trammed and the sample weights will allow the metal accountant to compute the production of coarse concentrates month by month.

Note that the metal accountant does not receive the daily routine analyses of materials in process, made as noted above. Instead he usually receives merely the analysis of the "monthly sample" representing the average of all coarse concentrates produced during the month. This sample is made up in the sampling department by preserving the same small fraction of each shift sample; this sample being proportional to the production for that shift. At the end of the month all of this material combined will represent a weighted average of the production for the month. The analysis when multiplied by the gross monthly production will give the quantity of each metal or oxide produced in this particular commodity.

The daily samples of the coarse concentrates may vary within limits around 12 per cent copper; the variation is a matter of concern for metallurgist and millman, but the metal accountant gets only the analysis of the monthly sample, which may read:

Moisture.....	5.75	per cent
Copper.....	12.22	per cent of the dried sample
Silver.....	3.90	ounces per ton
Gold.....	0.018	ounces per ton
SiO ₂	20.73	per cent
FeO.....	33.25	per cent
S.....	33.75	per cent
Al ₂ O ₃	4.40	per cent
CaO.....	0.28	per cent

From a consideration of his various weights the metal accountant arrives at the conclusion that 18,020 tons of coarse concentrates have been produced, which figure as follows:

Dry weight.....	33,968,691	lb.	a
Copper.....	4,154,638	lb.	
Silver.....	66,245	ounce	
Gold.....	311.5	ounce	
SiO ₂	7,037,466	lb.	
FeO.....	11,315,604	lb.	
S.....	11,475,725	lb.	
Al ₂ O ₃	1,493,861	lb.	
CaO.....	96,941	lb.	

This represents the total production as coarse concentrates for the period in question, and these figures are placed on his balance sheet in the proper places.

In a similar manner the fine concentrates, slimes and tailings are automatically sampled before reaching the storage bin, the resulting sample being a measure of both the quantity and quality of the product. In the case of fine concentrates, the weights of the carloads trammed from the bins to the calcine or other departments will serve as a check upon the production. In case the slimes are retreated, the metal in the slime plant is carefully accounted for in a similar manner as in the concentrating department, and these figures will serve as a check against slime production in the concentrator. Slime ponds and slime storage piles may be inventoried by quantity estimation by the civil engineering staff at intervals of twelve months in case the accumulation is very large, although, in general, monthly estimates will involve no more work in the totality. For estimates of the amount of tailings, reliance must be placed on the weights of the product of the automatic samplers; a check may be had by figuring all material not otherwise accounted for as tailings. Such a proceeding should be followed with circumspection, as it is liable to lead to numerous inconsistencies in the final figures for the various substances; but worse, it will cover up a multitude of sins of omission.

Accounting of Furnace Materials and Products

More attention is usually paid to the metal accounting of the furnace departments' receipts than elsewhere in the plant, for even in the most carelessly run plant, smooth working of the furnaces demands a properly balanced and weighed charge. The blast-furnace storage bins, for instance, may contain sections for first-class ore, second-class ore, custom ore, lime rock, briquettes and coke, each of which is weighed and sampled before delivery and which is drawn out in definitely weighed quantities in making up the furnace charges. With the aid of the monthly inventory, this material can be closely accounted for, as can also such intermediate and retreated products as concentrates, calcine barrings, converter and refinery slag, matte and smelter cleanings.

After once entering the furnace, however, the adequate tracing of the material is not so easy. The ordinary products are matte, slag, flue-dust and fume. Of these the matte is most simple to estimate. The quality is determined by filling one or two small ladles from the stream when tapping a pot of matte from the furnace or settler, and forwarding the buttons cast from each furnace to the laboratory for analysis. The quantity is determined by taking the gross and tare

weight of each ladle as it goes to the converter department, either on a platform or track scale, or if handled overhead, by automatic scales hung from the crane. The weight of matte skulls shaken out of the ladles for retreatment is found similarly.

If granulated, the slag is sampled, estimated and analyzed similarly to the procedure for concentrator tailings. If handled in pots, the sampling is done in the same manner as sampling matte, and the contents can be weighed on the way to the dump.

Difficulties of Estimating Flue-Dust and Fume

The estimation of flue-dust and fume is not so easy and in most cases the figures used are little more than guesses "by difference." Metallurgists have recently become very much alive to the fact that a close scrutiny of feasible methods of reducing the quantity of these elusive substances will pay handsome dividends, not only directly in values and retreatment charges saved, but indirectly in expensive "smoke suits" and damages averted.

By flue-dust is meant the finely divided solid matter carried in suspension from the furnace top by the more or less swiftly moving gases and which quickly settles as the velocity and carrying power of the smoke is reduced when passing through the larger flues leading from the furnace department. These flues are provided with hopper bottoms and large quantities of dust

vice should be used which will extract a representative portion of the passing gases without condensation of the fume, or loss of the very fine dust. A thorough study of the varying velocities of the different portions of the gas stream is also necessary in order that the curves drawn by the draft gage and recording thermometer may be transformed into cubic feet per minute.

Analytical skill and engineering ability of a high order is necessary to properly sample and estimate the conditions existing in the upper part of the flue system from dust chamber to top of chimney, but its expenditure will amply repay the company whose policy is sufficiently enlightened to realize the offensive and defensive value of accurate, complete and trustworthy information as to conditions in this part of the smelter. Flue and chimney jobs are usually dreaded by members of the staff, yet under proper design and management these units can become a veritable gold mine, and under the opposite conditions a theft of profits and a public nuisance.

Metallurgical Accountant's Balance-Sheet

The method of accounting for all furnace departments (roasters, reverberatories and blast-furnaces) is quite similar each to each, and need not be further dwelt upon. As a general illustration of a page from the accountant's balance-sheet, that covering operations of a McDougall roasting department is appended in Table II. It appears here in a condensed form from

TABLE II—McDOUGALL ROASTING DEPARTMENT

Pounds per square foot hearth area per furnace day	149
Cost per ton	\$0.65
Disposition of product	

are drawn from them every day to be charged and re-melted in the reverberatory furnaces. Weighing and sampling this dust is a matter of routine. Inspection holes at intervals in the flue walls and roof are utilized by the engineers to make monthly estimates of the material in the flue, whence a balance on the quantity of dust deposited may be had. Incidentally, a monthly estimate of flue-dust in the system will prevent any overloading with accompanying disastrous results to supporting beams and columns.

Little of the fume and not all of the finest dust is deposited before the gases join smoke from other departments, or enter the main dust chamber. At the point of junction it will be necessary to sample and measure the quantity of gases from each department in order to fix the origin of the very fine material deposited in the main dust chamber or precipitation plant, as well as the gases and solids discharged from the main stack. A very carefully designed sampling de-

what would be desirable in practice, as ordinarily more than four different classes of materials are charged.

However, it is extensive enough to illustrate the form of such balance-sheets and will indicate some of the uses to which it may be put. For instance, there is a loss of 134,021 lb. of copper shown. The inquiring eye of the manager will immediately light upon this item. With the metal at a normal price of 15 cents a pound, this represents a value of \$20,000.00; evidently well worth hunting for. Doubtless a considerable proportion of this metal will be found in the fume, deposited in and above the main dust-chamber, and which item does not appear on this balance sheet. Yet, if all the products were accurately sampled and estimated, a roasting department (or any other department, for that matter) should show a true balance between the "treatment" and the "production." This, of course, represents an ideal which is unattainable owing to imperfections in the analytical and other processes involved, yet the aim of the entire technical staff should be to approach this ideally perfect balance more nearly each month. Would any auditor be content with his staff and organization should the money accounts of a cor-

poration, however big, show a leakage of \$20,000 a month; or accept the statement of the bookkeeper that he "thought it represented unavoidable wastage"?

Accounting in the Converter Department

The converter department receives a varied assortment of material which is sampled and weighed before delivery. Matte from the blast-furnaces and reverberatories is charged molten; each ladleful being sampled and weighed as described above. Ore, concentrates, matte skulls and various fluxes are sampled and charged from time to time in weighed boat-loads as the blow progresses. Scrap-copper from the refinery or outside sources used to cool the converter is handled and weighed by the boat. Spillings, accretions, floor-cleanings and other products originating and retreated in this department are not taken into account on the metal balance sheets for obvious reasons; however, a monthly inventory of such material will furnish the necessary information to appear on the balance as "material in process."

The main product of the converter department is, of course, anodes of blister copper. These are sampled by holding a flat, pan-like ladle over the freshly poured anode, catching the minute shot-copper which dances up from the surface during cooling. Anodes from each blow are carefully stacked up, cleaned of projecting fins and weighed over accurate scales as they are trucked into cars for shipment to the refinery. Converter slag is a more bulky product, which is handled and weighed between converter and slag-casting machines as it is transported by the overhead traveling cranes. Sampling is done by thrusting a cold iron rod to the bottom of the ladle and quickly withdrawing it—a thin layer of slag adheres which will easily shell off upon cooling. The gases and fume present the same difficult problem discussed previously and are handled in the same general manner. Converter spittings, accretions and other unfinished products are usually retreated as rapidly as they are formed, by charging them back into a blow, and, therefore, do not need to be analyzed or estimated, with the exception of any balance existing as "material in process" at the regular inventory.

The maintenance of such a system of metal accounting will cause small additional expense to the company. One or two young technical graduates stationed in each department about the works will gather the necessary samples, and in most cases may act as scalemen as well. Considerably more expense will develop upon the laboratory in order to run the necessary analyses; some little time will be required from the civil engineers at the first of each month to make the inventory, and at least one first-class bookkeeper will be required for the clerical work of tabulation. This organization, with the exception of the civil engineers, should be under the direct control of the metallurgist; who, of course, should be directly responsible to the management for the proper technical operation of the processes involved in metal recovery.

Value of the Metal Inventory

Doubtless the greatest value of the metal inventory will be its everlasting demand for perfection. In order that it may measure up to the standard maintained in the clerical department for the money accounts, the closest attention must be paid to the details comprising the basis of the metal accounts. In order that the account may balance, the *losses* must be located. It will test the cleverest wits to discover the location of some of these losses. But what is more natural than an effort to prevent them or at least curtail the unpreventable to the smallest possible amount? Unprevent-

able losses in large volume should immediately condemn a supposedly successful concentrator or furnace and will institute a vigorous search for a more successful substitute. No line of investigation will be more fruitful of real facts about a furnace process than a close study of the metal and material balances when these are constructed on a scientific basis.

As an actual instance of the value of such studies suggested by the author's experience, a certain concentrator section was guilty of producing what seemed to the metallurgist to be an excessive amount of slime. A squad of samplers and investigators (all young technical men) under the direction of a competent engineer, started out to find where the trouble lay. They investigated the production of slime from the unloading bins to the banner division and showed conclusively that the coarse-crushers directly in front of the ore-storage bins were the greatest offenders. In order to "get the copper" the crusher-men kept their machines choked all the time—in this manner not only cutting down the actual capacity of the crushers but largely increasing the fine produced. In this manner the Blake crusher actually produced a greater amount of fine per ton of material treated than did a Huntington mill. An automatic feeder was then designed and installed to feed each of these large crushers a steady stream of coarse material from which the large proportion of undersize had been removed. The crusher capacity was increased, the operating cost in labor and repairs decreased, and best of all, the amount of slime made by the concentrator showed a sudden and gratifying drop.

Cincinnati, Ohio.

Synopsis of Recent Chemical and Metallurgical Literature

Iron and Steel

Effect of Chromium in Hardening Steel.—Chromium is widely used in special steels, usually with other added elements. Experiments have shown, however, that a chromium steel has self-hardening properties, without the presence of tungsten and that within certain ranges of composition the element chromium has an even greater self-hardening effect than tungsten. Further experiments carried out along this line are described in a paper presented to the Iron and Steel Institute in London by Professors C. A. EDWARDS, J. N. GREENWOOD and H. HIKKAWA.

Previous experiments by Hadfield, Osmond and the present authors, had shown that the rate of cooling determined the self-hardening properties, and considering that marked differences of hardness were obtained at different rates of cooling the author thought it desirable to examine the following conditions: (a) At what critical rate of cooling this self-hardening property becomes manifest, (b) whether there are any variable factors which influence this critical rate, and (c) what is the nature of the thermal change, if any, under the conditions of cooling which produce hardening. In other words, to make a quantitative examination of, and extend upon the facts which were discovered so long ago by Messrs. Hadfield and Osmond.

The composition of the steel used in the experiments was as follows:

	Per Cent
Carbon.....	0.63
Silicon.....	0.07
Manganese.....	0.17
Chromium.....	6.15

The initial temperature to which the pieces were heated was found to have an important bearing on the self-hardening properties and its effect and the rate

of cooling were investigated with the following results.

This property of self-hardening is governed by the rate of cooling.

The critical cooling velocities which produce hardening varies with the initial temperature, being much slower as the temperature is raised. The extent of this variation has been determined for a wide range of temperature.

The appearance of self-hardening coincides with the presence of large quantities of martensite, and a diminution in the magnitude of the carbide thermal change.

The maximum hardness was obtained when the thermal transformation had been entirely prevented, and when this was accomplished the steel was purely martensitic in structure.

While, with the chromium steel which has been used, the cooling rates which produce hardening are extremely slow as compared with those which are obtained in the hardening of carbon steels by quenching, the two operations are fundamentally the same. In other words, a given rate of cooling which might be regarded as slow for carbon steels, really constitutes quenching in the case of some special alloy steels.

The precise cause of an increased initial temperature making the self-hardening more evident is not known with any certainty. The view which the authors provisionally hold at present is, that the chromium carbide (Cr_3C_2), which has been isolated by Professors Arnold and Read, first goes into solution as $(\text{Cr}_3\text{C}_2)_2$, i. e., Cr_6C_4 , and is then progressively dissociated into Cr_3C_2 as the temperature is raised. When the steel is again cooling these molecules only slowly reassociate, and thus the molecular effect of the dissolved chromium carbide is greater as the initial temperature and molecular dissociation increases.

Tungsten and Molybdenum

New Tests for Molybdenum.—In the March issue of the *Journal of the Chemical, Metallurgical and Mining Society of South Africa*, Dr. JAMES MOIR gives some new and sensitive tests for molybdenum. The first relates to the formation of a characteristic blue color which ordinarily appears as a fugitive tint in the first stage of reduction of molybdic acid by nascent hydrogen. The author has improved this test and secures a permanent blue color.

Hydrazine, N_2H_4 , forms in the writer's experience the best reagent for developing the blue color. A solution containing a trace of alkali molybdate when acidified with acetic acid and treated with a little hydrazine sulphate and boiled, rapidly turns deep-blue and retains this color on boiling. Hydroquinone may be used in place of hydrazine with much the same result. An analogous but more remarkable reaction, is that obtained when a slightly acid solution of MoO_3 is treated with potassium iodide (in some excess) and boiled for some time: iodine is slowly liberated and the solution turns blue. The use of phenylhydrazine for reducing molybdenum has been described by Spiegel and Maas (*Berichte*, 1903, p. 513), but the reddish coloration obtained is different and seems to contain phenylhydrazine. Simple hydrazine is an improvement.

The best known sensitive test for molybdenum is that in which the acid solution is treated with sulphocyanide and a tiny piece of zinc added, when a crimson coloration is obtained in a few seconds. If iron is also present the solution becomes blood-red on adding the sulphocyanide, but on adding the zinc this becomes colorless through reduction (to the ferrous condition) and after a few seconds becomes crimson if Mo is present. If the solution is strongly acid the coloration verges to red and is less sensitive; if nearly neutral the coloration

resembles that of permanganate. It is probably due to $\text{Mo}(\text{SCN})_3$. Another modification of the test for Mo in presence of Fe is to add stannous chloride to the acid solution until the yellow color just disappears and then add sulphocyanide.

Another well-known reaction for MoO_3 in the absence of iron consists in adding potassium ferrocyanide. Mineral acid must be present, and a russet-brown precipitate is obtained which still contains hexavalent molybdenum.

In the presence of acetic acid (not mineral acid) tannin (or gallic acid) gives a similar reaction, which has been known for some time. The writer has improved this by substituting pyrogallol or pyrocatechol for tannin. Either of these when added to a molybdic acid solution previously treated with sodium acetate gives a very sensitive orange coloration.

The System Tungsten-Molybdenum.—The following summary of the essential points in a research conducted by FRANK A. FAHRENWALD, is taken from the June *Bulletin* of the American Institute of Mining Engineers. The alloys of tungsten and molybdenum have received little consideration in the past; in fact the author finds but two references in German literature on the subject, and his own studies lead him to differ with previous investigators who believed in the existence of a definite compound between the two metals. The thermal equilibrium diagram is given in Fig. 1.

FIG. 1—THERMAL EQUILIBRIUM DIAGRAM

1. By compressing the mixed reduced powders of tungsten and molybdenum into briquets and then heating with an electric current in an atmosphere of hydrogen, alloys of this series were prepared varying in composition from 100 per cent tungsten to 100 per cent molybdenum.

2. The solidus curve for the series was located by means of optical pyrometer temperature measurements and checked by comparing the fusing current with a standardized wattage-temperature curve.

3. The equilibrium diagram for this series shows no critical points, appearing as resistance fluctuations, corresponding to a separation of a new phase. Its construction has been based upon this fact and upon results of microscopical analysis.

4. Curves for hardness, and for equiaxing temperatures, are smoothly convex, being typical of an uninterrupted series of solid solutions (mixed crystals).

5. As a result of thermal and microscopical analysis, the metals tungsten and molybdenum are reported to be completely isomorphous.

6. All alloys of this series are malleable and ductile under proper conditions.

Sulphuric Acid

Roasting and Acid Plants of Braden Copper Co.—In *Teniente Topics* for December, 1915, Mr. JOHN B. WISE publishes a descriptive account of the methods of roasting copper concentrates and producing sulphuric

For the reduction of the tetrachloride to tin the tube *b* must also be used. Tin tetrachloride vapor is admitted through *b* and pure hydrogen through *C*. Zone *C* is again heated to between 600 and 1000 deg. C., zone *B* to 500 to 600 deg. C., and zone *A* to 250 deg. C. The reduction takes place so that at the lower extremity of *b* and zone *B* dichloride is formed, which condenses partly in zone *B* and partly in zone *A*, and descends to *C*. It is there reduced to tin, which flows off through *d*. Any

FIG. 1—REDUCTION OF TIN FROM CHLORIDE

dichloride that may have been volatilized, returns through zones *B* and *A* to *C*.

For the reduction of titanium tetrachloride to trichloride the apparatus shown at the right is used. This apparatus is based on the use of process of St. Claire-Deville, consisting of quick chilling of the product previously highly heated. The reaction is given as follows:

In the apparatus titanium tetrachloride is introduced in the form of vapor through tube *b* and pure hydrogen through tube *c*. If it is desired to reduce only to dichloride, zone *C* is kept below 700 deg. C., for reducing down to metallic titanium, a temperature of 800 to 900 deg. C. is used. Zone *B* must be kept at about 500 deg. C., zone *A* is formed by what is known as a Deville tube. A heating device such as a carbon rod is indicated at *d*. Lower leading-in wires are shown at *g*. These also serve as scrapes, for detaching trichloride from the cold wall.

In zone *A* complete conversion into the trichloride takes place. The trichloride drops through *B* to *C*, where it is converted to titanium, titanium chloride, or tetrachloride. Finally, the lower part of *C* will be filled with titanium, while hydrochloride acid and hydrogen escape at the top. The gaseous reducing agent may be a mixture of carbonic oxide and water vapor, instead of hydrogen, and pressure may be used. (1,173,012, Feb. 22, 1916.)

Metallurgical Furnaces

Sulphating Ores Under Pressure.—HENRY B. Hovland, of Duluth, Minn., has patented both laboratory and commercial types of furnaces designed for dry sulphating at superatmospheric pressures. Either type of

furnace involves a container for holding and supporting the material treated; means for agitating the material; an outer casing for withstanding superatmospheric pressure; means for introducing the reacting constituents, such as air and SO_2 , into the apparatus; a bleeder valve, and means for introducing and discharging the material to and from the furnace. (1,164,187, Dec. 14, 1915.)

Annealing Furnace.—An annealing furnace designed to utilize coal, coke, oil or gas producer fuel is patented by CHARLES F. KENWORTHY, of Waterbury, Conn. The furnace consists of an annealing chamber, heated from the outside by allowing the products of combustion to pass through an annular chamber surrounding the annealing chamber. Bright metals can in this manner be annealed free from fire or oxidation and do not require subsequent polishing or cleaning. Below the annealing chamber and in communication with it is a liquid chamber. A number of platforms arranged on vertical supports, which are movable up and down and sideways, carry the work to be annealed. A hydraulic piston arrangement moves these platforms from the liquid up into the annealing chamber and then back into the liquid. An automatic valve at the top of the annealing chamber releases suction or pressure and prevents liquid from being drawn up into the annealing chamber. The gas producer may be placed adjacent to the annealing furnace and directly connected to it. Pyrometer thermocouples are joined to the vertical supports at each platform. (1,169,494, Jan. 25, 1916.)

Calcining Furnace.—A furnace designed for heating finely divided or granular carbon is shown in sectional elevation in Fig. 2, being the patented invention of WILLIAM R. CLYMER of Cleveland, Ohio. The calcining chamber 2 extends centrally from top to bottom of the furnace, and is fed with the material to be calcined from a hopper 3. The treated product is removed by screw conveyor 5 and discharged at 7. Surrounding the heating chamber is a tortuous passage 8 communicating with passage 9 which, in turn, is connected with an air supply. Another tortuous passageway 10 is in communication with a fan 12, the latter also being in connection with the calcining chamber by means of duct 13. Passages 8 and 10 merge into a combustion chamber 14 which communicates with passage 15 which ends in a stack or flue 16. The gases given off from the calcining mass in the heating chamber are drawn by the fan and delivered into passage 10 and thence in combustion chamber 14, where they are mingled with air entering through 8. This produces the heat necessary to treat the mass in the chamber 2. As the products of combustion pass through 15 to a point of discharge they give up heat to the material in the upper part of the chamber. As the charge descends in the shaft it will give up heat to the air in passage 8 and thus preheat it for combustion with gas in 14. (1,147,706, July 27, 1915.)

Sintering or Chloridizing Furnace.—A furnace designed to treat ore by roasting in a continuous oper-

New Barometric Condenser

The Ingersoll-Rand Company, 11 Broadway, New York City, is now offering to the trade complete steam condensing plants for all service conditions. This equipment includes the Beyer barometric condenser, for which the company has secured the patent rights, Imperial duplex and Ingersoll-Rogler straight-line, reciprocating, dry vacuum pumps and, where required, Cameron simplex and centrifugal pumps.

The Beyer barometric condenser is of the counter-current type, in which air and cooling water flow in opposite directions. The steam inlet is at the bottom of the condensing vessel, the water inlet above and the air removal opening at the top. The sheets of cooling water overflowing the pool at the inlet point meet the entering steam. The two are brought into intimate contact by conical baffle plates assisting the water to absorb to its full capacity the latent heat of the steam. The non-condensable air liberated in the condensing action rises through the falling water to the removal point at the top, being cooled to practically the temperature of the incoming water. It is also to be noted that ample opportunity is given for the removal of the air content of the water before it mixes with the steam. This not only facilitates the mixing process, but permits the removal of air and vapor at a comparatively low temperature, which is a distinct advantage as the reduced volume saves in vacuum pumpage horse power.

The steam inlet is of large diameter to secure low velocity and is hooded in such a way as to discharge the steam into the center of the condensing vessel. The air removal opening is also of ample area and is protected by a self-draining baffle and trap. This, it is said, positively prevents water being carried over into the vacuum pump.

The hot waste water is discharged through the self-draining tail pipe. This pipe straddles the hot well and rigidly supports the condenser.

The Imperial and Ingersoll-Rogler Vacuum Pumps

FIG. 2—SECTION OF BEYER BAROMETRIC CONDENSER

condensing unit serving a number of prime movers.

are of the manufacturers' standard type. They are high-speed reciprocating machines, wholly enclosed, automatically lubricated and are claimed to effect a floor space saving approximating 50 per cent over the more common slower speed vacuum pumps.

When a water pump is required to elevate cooling water to the condenser head Cameron pumps are provided. These may be either reciprocating or centrifugal, as desired. The Ingersoll-Rand Company, however, emphasizes the fact that, where the level of the cold well is of sufficient height above the hot well, the condenser will lift its own cooling water, dispensing entirely with a water pump.

The vacuum and water pumps, being independently operated, can be regulated to suit varying water temperatures and conditions, and this plant, in addition to its efficiency in general service, is admirably adapted for duty as a central condensing unit serving a number of prime movers.

Disc Crushers in Use at the Intermediate Stage

The Symons disc crushers, made by Messrs. Chalmers & Williams of Chicago, Ill., have proven highly economical as intermediate crushers. In most large plants crushing is done in several stages, the first break being made in heavy jaw or gyratory crushers, and the second break was formerly done by smaller jaw or gyratory crushers, or crushing rolls. It is in this second or intermediate stage of crushing where the disc crushers are used.

One of the features is that both discs turn in the same direction at the same speed so that there is practically no abrasion or grinding action between the two discs. The material fed through the spout is immediately distributed by centrifugal force and that portion sufficiently fine is thrown out through the opening between the discs against wearing plates in the hood and discharged.

The range of reduction is large, the product uniform, and the capacity per horsepower very high. The cost of operation, of course, depends upon the material being handled and local conditions. The cost of repairs ranges from under 1.5 cent to about $1\frac{1}{2}$ cent, the latter being high. In one plant crushing hard gravel the total cost for reducing material from $3\frac{1}{2}$ in. to $3\frac{3}{4}$ in., including every item of expense connected with operation, was 97 cents per 100 tons.

Another crusher made by the same company is the Symons fine-reduction disc crusher, which is only made in one size. This machine was developed primarily for receiving a feed $21\frac{1}{2}$ in. and finer, and crushing down to $\frac{1}{4}$ in. and finer. When used in this way the efficiency is very high and the cost for operation extremely low. It may be operated either wet or dry and the product is very uniform. The New Cornelia Copper Co. of Arizona, recently ordered thirteen of these machines for crushing dry. There will be three units with three crushers in each unit and a fourth unit to be held in reserve. The three units of nine crushers will handle material discharged from gyratory crushers set to $3\frac{1}{2}$ in. and deliver a product all practically $\frac{1}{4}$ in. and finer.

FIG. 1—OUTSIDE VIEW OF BEYER BAROMETRIC CONDENSER

SYMONS FINE REDUCTION DISC CRUSHER

These nine crushers will handle 4,000 tons in 16 hours and based upon tests extending over a long period, will not use over 360 hp.

As a result of extensive tests made upon these machines it has been found that by changing the upper disc slightly and the feed opening, material can be handled up to 4 in. ring and reduced at once to $\frac{3}{8}$ in., $\frac{1}{2}$ in. or $\frac{3}{4}$ in. When so operated the capacity is practically all that can be fed into the machine and may be 50 tons per hour and up; the power in no case should exceed 60 hp. and usually would not be over 40 hp.

Personal

Mr. F. L. Craddock has been appointed manager of the New York office of the Pfaudler Company, Rochester, N. Y., and Mr. R. B. Kilmer has been appointed manager of the Chicago office.

Mr. George W. Fraser, formerly superintendent of the smelting department of the Arizona Copper Co. at Clifton, Ariz., has been appointed superintendent of smelting at the plant of the American Copper Syndicate, Ltd., at Aroa, Venezuela. He left for his new post July 6.

Mr. Robert C. Gemmel, general manager of the Utah Copper Co., has been elected a director of the company. Mr. John M. Hayes, assistant cashier at Salt Lake City, has been appointed treasurer.

Mr. S. S. Jones has resigned his position as superintendent for the Tom Reed Gold Mining Co. in the Oatman district, Arizona. The entire management of the company changed on June 1 and practically all of the new staff are former employees of the Gold Road Co.

Mr. Bernard MacDonald has moved his office from Los Angeles to 715 Mills Building, El Paso, Texas, where he will continue his professional work. At present he is collaborating with the engineering staff of the Alvarado Mining & Milling Co. in designs for increasing the capacity of that company's mill at Paral, Chihuahua, from 400 to 600 tons per day. The machinery has been ordered and will be installed as soon as peace is established in Mexico.

Mr. Richard K. Meade, consulting chemical engineer and cement expert of Baltimore, Md., was elected to membership in the Phi Beta Kappa Society at the recent commencement of the University of Virginia, in

recognition of his attainments in the field of chemical engineering and especially hydraulic cements. As the University of Virginia confers no honorary degrees election to this society is the highest gift the University may confer on its distinguished alumni.

Mr. Guy C. Riddell, formerly smelter superintendent for the A. S. & R. Co., at East Helena, Mont., has been retained to investigate the lead smelting practice of the same company.

Mr. Gilbert Rigg, formerly in charge of research work for the New Jersey Zinc Co., has been appointed to a consulting position in the zinc smelting department of the Broken Hill Associated Smelters Proprietary Co., Ltd., Port Pirie, South Australia.

Mr. O. C. Schaefer, formerly superintendent of the National Radium Institute of Denver, has accepted an appointment as superintendent with the Chemical Products Co. of Denver, manufacturers of molybdenum, vanadium and barium products.

Mr. E. Bryant Thornhill has accepted a position with the Metals Recovery Co., Ltd., Cobalt, Ontario, Canada.

Mr. Carl J. Trauerman, mining engineer and metallurgist, has resigned the position of mill superintendent of the August Mining Co., Landusky, Mont., and is inspecting the properties of the Beaver Creek Mines Co. of Zortman, Mont. After examining mines in the Kendall, Elliston and York districts of Montana he will return to his headquarters at Butte, Mont.

Prof. A. L. Van Hecke of the University of Louvain, Belgium, is in this country studying the latest developments in steel and iron. He attended the recent meeting of the American Society for Testing Materials at Atlantic City.

Mr. A. Van Zwaluwenburg is now chemist for the Nipissing Mines, Ltd., Cobalt, Ontario, having given up his position with Walter Harvey Weed in preparation of the Mines Handbook.

A number of changes have recently taken place in the U. S. Bureau of Mines. Mr. C. A. Wright, who has been in the Joplin district for some time, has been transferred to Salt Lake City. From the Denver office of the bureau, Mr. Alan Leighton has gone to the Goodrich Rubber Co., Akron, O.; Mr. J. C. Morgan has been transferred to Salt Lake City; Mr. H. A. Doerner has been engaged by the Chemical Products Co. of Denver, and Mr. C. F. Whittemore has accepted a place with the Schlesinger Radium Co. of Denver.

Mr. R. J. Weitlaner, formerly with the Midvale Steel Company, is now in charge of a Heroult electric steel furnace at the plant of the Hess Steel Corporation in Baltimore, Md.

Obituary

Lucius L. Wittich, mining news editor of the Joplin (Mo.) News Herald, died at Joplin on June 25, 1916. For many years his name had been prominently identified with the lead and zinc industry of Missouri and particularly of the Joplin district, through his contributions to the popular and technical press and his skill in gathering and presenting statistics on lead and zinc production. He had the latter feature well organized and the results were considered reliable and representative. As a leader in local mining news circles, his loss is keenly felt and his place difficult to fill.

Alvin R. Kenner, graduate mining engineer from the Colorado School of Mines in 1907, was found drowned in a lake near Grass Valley, Cal., on July 5. Mr. Kenner was superintendent of the Rio Plata Min-

ing Co. in Mexico and visiting in the States at the time of his death. He was an occasional contributor to the technical press and was favorably known among his engineering colleagues.

Industrial Notes

Fluorspar in 1915.—The year 1915 was a record year in the fluorspar industry in the United States, according to a Geological Survey Report by E. F. Buchard. The output of 136,941 short tons exceeded that of the next highest year 1912 by more than 20,000 tons, or nearly 18 per cent. The general average price of domestic fluorspar has declined steadily in the last four years, largely as a result of improvements in methods of milling and handling large quantities in the Illinois-Kentucky District, and this price was lower in 1915 than at any time in the last ten years.

Standard Methods of Gas Testing.—The second edition of this work has just been published by the Bureau of Standards as Circular No. 48. The first edition was compiled to fill the need for a publication which could be accepted as a standard guide to the methods of testing gas used for illuminating and heating purposes. The second edition is a revision of the first, embodying new suggestions and the results of work carried out by the Bureau. The different sections deal with the following subjects: location and general equipment of laboratory, measurement of gas, measurement of heating values, candlepower determination, determination of impurities, pressure records, meter testing, specific gravity, dew point and atmospheric humidity.

Rennerfelt Electric Furnaces.—Hamilton & Hansell, 17 Battery Place, New York, announce the sale of the following Rennerfelt furnaces:

One 2 3-ton, 150-kw. to the Tungsten Products Co., Boulder, Col., for making ferrotungsten. Two further furnaces, one 3 tons, one 6 tons, for making ferrotungsten. Not at liberty to name the party at this time, although the furnaces are for domestic use. One 3 $\frac{1}{2}$ -ton, 225-kw. for making steel to the Samson Iron Works, Stockton, Cal. One 1 3-ton, 100-kw. for bronze to the Titanium Alloy Mfg. Co., Niagara Falls, N. Y. One 1 3-ton, 100-kw. for bronze to the Gerline Brass Foundry Co., Kalamazoo, Mich.

In addition to this, three additional furnaces were sold in Europe, making sixty-four Rennerfelt furnaces contracted for now in the world, fourteen of which are for the United States.

Dividends of German Companies.—The annual statements of the most prominent German companies for 1915 show that the number of companies announcing no dividends for the year was relatively small compared with the total number reviewed, according to a U. S. Consular report. It also appears that an excessive decrease in dividends was only declared in a minority of cases, and only by undertakings that were either insufficiently financed originally or were manufacturing articles of luxury and products intended for export. The porcelain and glass industries as well as the potash works, which generally exported more than half of their entire production, naturally had to declare greatly decreased dividends because the loss of exports could not be replaced in other ways. The cement factories, which were not in the best of condition in times of peace, have suffered greatly.

In general, decreased dividends were reported by the industrial lines not actively engaged in the manu-

facture of war supplies. The limitation of production in many industries has not only been caused by a decreased demand but by a lack of producing facilities. The industrial lines in which relatively high dividends were announced are principally mill products, chemicals, paper, coal, iron, steel and textile industries.

The D'Olier Centrifugal Pump & Machinery Co., Philadelphia, Pa., describes in the June issue of its bulletin wood screw type pumps for irrigation and drainage service, centrifugal pumps and multi-stage pumps. Descriptions of the D'Olier-Weston centrifugal pumps are also included.

Large Increase in Coke Production.—The coke production in the United States in 1915 was 41,581,150 short tons, an increase of 20 per cent over the 1914 production. Of this total, 34 per cent was by-product coke and the balance was made in bee-hive ovens. The increase over 1914 in the output of by-product coke was 25 per cent, and in bee-hive coke 18 per cent. The quantity of by-product coke made was the greatest yet recorded.

Lignite in South Dakota.—In Perkins and Harding Counties in South Dakota, it is estimated by United States Geological Survey that there are 1,000,000,000 tons of lignite. The estimate is given in Bulletin 627, just published. At present this lignite is mined for local domestic use and as fuel for steam plow equipments. Experiments made by the United States Geological Survey and later at the Bureau of Mines and the North Dakota School of Mines have proved that this lignite, on briquetting, makes a very superior fuel. When burned without briquetting in a producer-gas engine it is more efficient than the best coal when burned under boilers.

Dyestuff Industry Developing in Japan.—According to a representative of the Mitsui Mining Co., as published in Commerce Reports, all the by-products of the Government Iron Works, the Mitsui Mining Co., the Mitsu Bishi Co., the Tokyo Gas Co., the Osaka Gas Co. and other factories are being fully used. The supply of coal tar now exceeds 60,000 tons. In its distillation many big commercial interests are engaged. The foremost of these is the Nippon Dyestuff Co., which has a capital of 8,000,000 yen (\$3,988,000). It profits from Government protection under the law for the encouragement of chemical and dyestuff industries, although the concern is still far from actually being in operation. Gas companies in Osaka and Tokyo have also taken up the manufacture as a subsidiary branch, as they have a good supply of coal tar at their disposal. Aniline salt and induline are already marketed by the Tokyo Gas Co. The Mitsui Mining Co. has succeeded in producing a variety of dyes from the coal tar produced by its works at Miike. A month hence the company hopes to extend the list of its products so as to include additional derivatives of benzol, carboic acid, salicylic acid and picric acid. There are also many minor enterprises engaged in this branch, including the Osaka Chemical Industry Co. and the Kobe Seikojo. These produce several artificial dyestuffs and contribute much to the rapid development of the important new industry in this country. There are still many difficulties to be overcome. In the first place the scarcity of auxiliary materials hampers the efforts of manufacturers. Sulphuric acid is obtainable, but there is said to be no stock of oleum in this country. Caustic soda and soda ash are also scarce. Unless these materials can be more freely supplied the development of the dyestuff industry will be seriously retarded. In the second place dye-

stuff producers are confronted with a grave problem in finding a market for by-products. The local demand is small. The success of dyestuff enterprises depends largely on the advantageous disposal of these by-products. Lastly, there is a pronounced technical difficulty to be overcome. As the enterprises are developed the equipment necessarily becomes more and more elaborate, and experts' difficulties in handling the problems are all the more enhanced.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath Apparatus

704,401, July 8, 1902, Julius Taluan of Philadelphia, Pa., assignor of one-half to Henry W. Scattergood of Philadelphia, Pa.

Relates to a method of framing glass suitable for making stained glass windows, and refers to an earlier application filed in 1895, serial number 572,318. In the present invention, a conducting support such as sheet lead, has placed upon it pieces of wax or other non-conducting adhesive which are of the same shape as the glass pieces, but are slightly smaller, so as to leave an edge around the under side of the glass pieces which are supported upon the smaller wax pieces. Spaces are also left between the several glass pieces. The assembled mass is now placed in the depositing vat, and metal deposited upon the lead sheet between the pieces of glass, and continued until it overlaps at the upper edges thereof, the deposit upon the lower side overlapping the bottom edges on account of the wax sheets having been cut smaller and providing the free edge above referred to. The united glass pieces are then suitably framed.

709,513, Sept. 23, 1902, Henry W. Scattergood of Philadelphia, Pa.

Relates to a method of framing glass or other materials, for making stained glass windows, mosaics, and the like, and consists in securing the glass pieces to a piece of tissue-paper, leaving spaces between the glass pieces, filling the spaces with a starch composition or the like which may be subsequently removed by washing, inclosing the entire object in a frame and filling the frame with sand or other easily removable packing and securing the sand in the frame by a removable cover. The frame with its contents is now inverted, and the tissue-paper removed; a coating of graphite or bronze powder is applied to the entire back of the glass pieces and starch filling, and conductors connected thereto. A second frame is then attached to the first and filled with wax. The entire mass is now inverted, the sand and starch filling removed, and then immersed in an electrolytic tank, deposition of metal being effected upon the graphite in the spaces between the glass pieces to the desired thickness so as to securely hold the glass. The spaces may be partly filled with metal filings if desired to reduce the quantity of electrodeposition required. The structure is now inverted, the wax backing and graphite removed, and the deposition of metal continued upon the metal seams between the pieces of glass until they are securely held on both sides of the assembled window.

Aqueous Bath, Cathodes Metalizing

7,821, Dec. 10, 1850, George Mathiot of Washington, D. C.

Relates to coating a cathode with a deposit which facilitates subsequent separation of an electrodeposited coating. For engraved metallic plates, etc., an electrodeplate of silver is first deposited, this silver deposit is chemically cleaned, and is then treated with an alcoholic solution of iodine which is then quickly drained off, and the plate exposed to the light for one or more hours, when it acquires a "leaden" appearance. It is now immersed in the electrolyte and the deposit proceeded with by the usual methods. When completed the deposit is readily separated from the cathode plate. For large cathodes, of 10 sq. ft. or more surface, one grain of iodine is dissolved in 20,000 grains of alcohol; for smaller plates, stronger solutions may be used.

23,633, April 12, 1859, John W. Wilcox of West Roxbury, Mass.

Relates to making rolls for printing, paper-making, etc., and consists in covering an iron or other metal roll with a strip of copper wound as a helix, the joints between the turns of the strip soldered, and the strip itself may be soldered throughout to the roll. The completely covered roll is then turned or ground perfectly true, and electroplated with a thick coat of copper. It is then ready for use.

Book Reviews

The Molecular Volumes of Liquid Chemical Compounds. By Gervaise Le Bas, B. Sc. Octavo (15 x 22 cm.), 272 pages, 9 illustrations; price, \$2.25. London and New York: Longmans, Green & Co.

This treatise is for advanced students of chemistry, and is intended to elaborate the theory of molecular volumes of Kopp in the light of modern researches. The author retains Kopp's conception of molecular and atomic volumes and of the additive principle in this connection, but adds to these several modifications, such as using several atomic volumes for oxygen and nitrogen in different types of compounds. By also revising the values of the atomic volumes of carbon and hydrogen, used by Kopp, many constitutive properties of compounds are thus revealed and a fairly consistent theory of molecular structure built up. The whole is a report of progress, worth careful study by all interested in physical chemistry, but the conclusions lack finality—which holds out good promise of still further progress.

Steel and Its Heat Treatment. By Denison K. Bullens, Consulting Metallurgist. Octavo (14 x 22 cm.), 431 pages, 223 illustrations; price, \$3.75. New York: John Wiley & Sons, Inc.; London: Chapman & Hall, Ltd.

This is a good treatise on annealing, hardening, tempering, toughening, and case-hardening of carbon, nickel, chromium, chromium-nickel, vanadium, manganese, tungsten and other alloy steels, together with chapters on pyrometers, critical range determinations, and mechanical testing. We find it a very readable and interesting book, with a mass of well-arranged and useful information. It is, however, far from complete, and may disappoint because of its omissions, such as the special treatment of high-tungsten steel for magnets and high-speed tools, the meager description of heating baths and of electric heating furnaces for automatic heat treatment. We protest, also, against "chrome" being generally used instead of "chromium" throughout the book—a point on which the printed treatise should rectify current workshop carelessness. With some such additions and corrections as above mentioned the book could be made considerably better.

Why People Should Interest Themselves in Electrochemistry

It is remarkable how the conception of the scope of chemistry has recently grown in the general public's mind, after chemistry had been synonymous with drugstores so long to so many people. Everyone is now acquainted with at least one other field of chemical endeavor—dyestuffs—and thus chemistry has made a clear advance of 100 per cent in popular estimation. Among technical men, however, it is electrochemistry that is now attracting greatest attention. Of course, as long as Faraday's law has been taught in schools, those who had to learn it knew of electrochemistry. But for many its scope was restricted to batteries and plating. Naturally electrical engineers knew better, as they had to buy their copper from the electrolytic copper refinery and the generating capacity of an electrolytic refinery is sufficiently impressive to gain the respect of any engineer. No wonder that many a man who had been interested in lighting and traction systems is now attracted by electrochemistry which has no such sources of trouble as a public service commission. Finally the power famine at Niagara—deplorable as it is—has had at least one good result—that attention has been attracted to the nation-wide economic importance of the Niagara electrochemical industries. (Compare the report on page 115 of this issue.) And the doubling in the number of American electric steel refinery furnaces during the last year is but another illustration of the same story.

There are two essential reasons why American engineers should interest themselves in the American electrochemical industries. First, because they are of fundamental economic importance for the whole country. Second, because they are thoroughly American in origin and thus a source of profoundest pride for the nation. We hope that many engineers, and especially electrical engineers, will take advantage of the meeting to be held by the American Electrochemical Society in New York in September, to make themselves acquainted with American electrochemists. There is no more congenial crowd to mix with.

University and Industry

During last winter the New York Section of the American Chemical Society held a series of meetings for the purpose of discussing the various phases of the interrelation between science and industry and promoting a heartier co-operation between the two. All of these meetings, which were fully reported in this paper, were very interesting and very suggestive. But, after all, it is human, all too human, to listen

attentively and approvingly to the preacher's admonition on festival occasion and forget promptly the good intentions in the pressing every-day duties of the morning after.

In this issue we record a real deed. The article by Prof. W. H. Walker on the new chemical engineering course of the new Massachusetts Institute of Technology tells how a splendid idea of most direct co-operation between university and industry is being transformed into reality with a boldness of conception that is unique in the history of chemical education. It is a grand pioneer experiment in education. We heartily wish that it be successful in such overwhelmingly convincing style that in the end it will be remembered but as the pioneer experiment and the forerunner of many others.

The Steel Production Statistics

There have lately appeared the statistics of production in steel ingots, steel castings, and rolled steel in 1915. The figures are studied with particular interest on account of the changed character of demand last year, whereby a large tonnage of steel was rolled for shell making, with unusually heavy discards, and one naturally looks to see whether the statistics indicate the production and consumption of an unusually large tonnage of scrap in the open-hearth furnaces.

One interesting comparison to be made is between the tonnage of basic pig iron and the tonnage of basic open-hearth ingots and castings. The production statistics, with the percentage of pig iron to steel, are given below, also the production of duplex steel for the year for which such statistics were gathered:

	Steel, Gross Tons	Pig Iron, Tons	Proportion, Pig to Steel	Duplex Steel, Gross Tons
1896	776,266	306,406	39.3	
1897	1,056,043	556,444	52.7	
1898	1,599,412	785,441	50.1	
1899	2,080,426	985,023	47.4	
1900	2,545,091	1,072,376	42.1	
1901	3,618,993	1,448,850	40.0	
1902	4,496,533	2,038,590	545.2	
1903	6,753,126	2,040,726	30.2	
1904	5,106,367	2,182,104	42.7	
1905	7,815,728	3,195,179	52.5	
1906	9,658,760	5,018,674	52.0	
1907	10,579,315	5,375,219	50.4	
1908	7,140,425	3,000,114	42.1	
1909	13,417,472	5,250,225	61.9	
1910	15,292,329	9,081,608	79.5	
1911	14,685,932	8,520,020	58.0	
1912	19,641,502	11,417,336	58.1	
1913	20,344,626	12,536,693	61.6	
1914	16,271,129	9,670,687	59.4	
1915	22,368,172	13,093,214	58.7	1,781,491

Thus the largest proportion of scrap used appears to have been in 1901. For a number of years, ability to hold down the proportion of pig iron was due, in part at least, to the diversion of Bessemer scrap from the Bessemer converter to the basic open-hearth furnace. In 1906 there occurred the maximum production of Bessemer steel, its production having decreased since then, while the production of basic open-hearth steel has more than doubled. The percentages given in the above table are not, of course, identical with the average percentage of pig iron charged to the furnaces, but the annual fluctuations are a trustworthy index. The maximum proportions of pig iron fell in 1909 and 1913. The increase in the use of direct metal has made it convenient to use larger proportions of pig iron. In

1915 no less than 73.7 per cent. of all the basic pig iron produced was delivered molten, while 13.3 per cent. of the production was made for sale, and was, therefore, necessarily cast. It is to be observed that the amount of duplex steel produced has really not been large, and this process has, therefore, not thus far decreased to any extent the proportion of scrap used in the basic open-hearth furnaces as a whole. Duplex steel is, of course, reported as part of the total of basic open hearth produced.

The quantity of scrap used in the basic open-hearth furnace in 1915 was only slightly less than in immediately preceding years. There is no doubt that there were larger supplies on account of the liberal cropping practiced on several million tons of steel made in the year. The effect of the extra scrap production appears to have been seen chiefly in an influence operating to prevent the scrap market from advancing as sharply as did the unfinished and finished steel markets.

The figures cited above are suggestive as to the consumption of scrap. As to the production of scrap, there are other figures that can be studied, by making comparison between the production of steel ingots and of finished rolled steel. The statistics of rolled steel are gathered in such form that comparisons from year to year can readily be made. "Rolled steel" includes, in general, material weighed in the form in which it leaves the hot rolls for the last time, but, of course, after shearing. Thus, the statistics refer to sheets and black plates, rather than to sheet bars; to skelp, rather than to welded pipe; and rods, rather than billets or wire. Rolled forging billets and all billets, etc., for export, are included, as otherwise the material would be lost to the statistics. The comparison is as follows:

	Steel Ingots, Gross Tons	Rolled Steel, Gross Tons	Proportion of Rolled Steel
1912	30,284,682	23,019,259	76.01
1913	30,280,130	23,112,986	76.34
1914	22,819,784	17,202,420	75.38
1915	31,284,212	23,098,091	73.83

There is scale produced, and in comparing different years there may be slight divergences due to there being larger proportions of light material rolled in some years than in others. Generally speaking, however, there was evidently much larger cropping of ingots and billets in 1915 than in any other year. It is a fact, moreover, that some mills produced ingots late in 1914 for stock, the demand being very light, such steel contributing to the ingot statistics for 1914 but to the finished-steel statistics for 1915; and thus the rolled steel in 1915 may have been less than normal by approximately 3 per cent. of the ingot production.

The fact that the statistics indicate the production of scrap, or billet discards, rather than its consumption, may be explained, in part at least, by the material accumulating at works.

Bleeding Kansas

Kansas is always in the throes of something or other. We hark back to the time when, to all appearances, single-handed and alone, Kansas was fighting the demon rum, with only the encouragement of old Uncle Jehoshaphat Maine, who shouted his hurrahs—between drinks.

Then came Populism and Sockless Jerry Simpson, the while the Kansas farmers ploughed deeper and deeper and bethought themselves of new notions. The trouble with Kansas is that she is never satisfied, and as time rolls on, and as some of us grow old and begin to wish that she would settle down and become conservative and sensible, like other folk, Kansas doesn't settle down. It is a nervous and unbiddable community. There is abundant tradition, all over the world, that if anybody has a new idea he should be snubbed and told to go back to that station in life to which, in the minds of conservative persons, it hath pleased God to call him. Such a station of life, in the minds of the truly conservative, is nearly always in the back row.

But Kansas is not conservative. It has no respect for tradition or established forms or justification by cult. It is a nervous, restless place, and is not to be recommended to elderly gentlemen of a gouty or rheumatic tendency, with fixed habits of mind.

At the Kansas State University at Lawrence, as soon as the late Robert Kennedy Duncan began to display chemistry so that it became attractive to the man on the street, they called him to their chair of industrial chemistry. Then when that man o' dreams conceived the idea of establishing industrial fellowships with the view to applying chemistry to daily life and the affairs of men, they took it up immediately, and it is still going at full tilt. Out of this the Mellon Institute of the Pittsburgh University was born, and in it is indicated one real link between the universities and industry. No one who has the development and spread of chemistry at heart can visit the Mellon Institute and observe their methods of attack in industrial research, without becoming inspired with the belief that that is a real thing. The idea comes from Kansas.

The students of chemistry and metallurgy at Lawrence have just issued the first number of an annual paper which they call *The Kansan Chemallurgist*. It has twenty-four pages, and it is utterly devoid of sporting news. That is another innovation! Who ever heard of a college paper without even a baseball or a football score? There is no mention of the hockey team or the glee club or of the most popular man of the Class of '16. This seems unusual enough to be all wrong—to the conservative mind. And yet that magazine is full of readable stuff. It begins with what might be called an horn solo about Kansas and her industries. We learn that in 1914 the value of products manufactured in that State was \$328,936,964. The two leading industries are slaughtering and meat packing, and flour milling; and we might mention right here that there is a crying need for chemical research in regard to flour that has not yet been accomplished either in Kansas or Minnesota or Buda-Pesth or anywhere else as yet. Then come zinc smelting and refining along with the production of sulphuric acid, cement, brick and tile, glass, leather goods, salt, paint and varnish, pottery, dairy products, and a lot more. The zinc production in 1915 was over \$40,000,000 worth—but that may be high-water mark. The cement industry has developed into the millions in output; there are twenty-three glass works, and, alas! it

grieves us to repeat it: "Kansas is not to be left out of the coke industry and can *boast* of sixty-seven bee-hive ovens in the southeastern part of the State." (The italics are ours.) Let us hope that Kansas will soon cease to boast over bee-hive coke ovens.

There is an article by L. S. Bushnell, who urges young chemical engineers to get into the works rather than into the laboratory to the end that they may learn to produce, and Dr. Charles H. Herty comes along with the advice not to jump into jobs too soon at the expense of adequate preparation. But this is said with such grace and *savoir faire* that it sounds less like advice than like a good thing to know. The university has a department of State Chemical Research under Prof. W. A. Whitaker, and this is conducting investigations in the following subjects: prevention of zinc mineral wastes by means of flotation, salt deposits of the State combined with a potash quest, survey of natural gases, removal of iron and softening of municipal water supplies, disposal of municipal sewage and studies of the yucca plant and of sunflower oil.

We learn also that there is a K. U. Chemical Club which meets Wednesdays in which the following papers have been read by members of the faculty during the current year: standardization of chemicals and drugs; effect of radio-active substances on plant growth; ductless glands; micro-metallography of ores in the Comstock Lode; notes on salicylic acid and its allies; chemistry 3000 years ago, antaphylaxis and antaphylactic reactions, enzymes and enzyme action, electric culture, putting your uncle to work, and preparation and use of hydrogen during the European war. Then, as though resolved to be in the fashion, they have a Society of Chemical Engineers with papers by research students and men of affairs in the industries. We find that the chemical faculty of the University numbers twenty-two and the record of the alumni indicates that they stick to chemistry. Here and there one falls from grace, as in the case of a member of the class of 1892 who is now literary editor of one of the leading magazines published in New York. Six are fellows of the Mellon Institute.

The purpose of these remarks is criticism: criticism of those young men of Kansas for their own good. We have mentioned Sockless Jerry Simpson with what was designed for scorn, and we do not approve of the name "Chemallurgist." We think the English language has enough burdens to bear without inventing new ones for it. But when we have said this we can find no more fuel for our critical fire. It seems as if those fellows were live wires. We shall put their magazines away in our files and expect to read their names again. Somebody out there seems to know how to teach and to inspire young men, and the material appears to be of good quality.

Of course, Kansas will continue to bleed. She must bleed in order, to quote Scripture, "that the prophecy may be fulfilled"; that we may continue to use the expression to which our tongues have accustomed themselves. But it doesn't seem to do Kansas any harm. She appears to be taking care of herself. We should like to see some other States do a little similar bleeding.

Readers' Views and Comments

The Dyestuff Tariff

To the Editor of Metallurgical & Chemical Engineering

SIR:—In reading over the copy of the "Dye Stuff Tariff Before Congress," reported on page 65 of the July 15 issue, I notice that several articles such as hydroquinone, pyrocatechin and phenolphthalein and possibly some others, have been omitted in the proposed bill, and I have wondered whether this omission was intentional or accidental. The necessity for protecting these articles is not by any means imaginary, since some of them have been made the subject of dumping by the producers abroad, much to the detriment of our manufacturers. I regard the injection into tariff provisions of a really efficient anti-dumping clause as of even more importance to our industries than a prohibitive tariff rate.

That very unfair practices have been indulged in by importers is known to all of us in the profession, and the law makers need careful instruction if this is to be really avoided in the future.

When I was running for Congress two years ago in the 26th district, I had a letter from the president of one of our largest chemical companies wishing me success. For said he, "We have not a single person in the House of Representatives to whom we can go and talk intelligently with the expectation of being understood."

EDWARD HART.

The Ball Mill for Regrinding

To the Editor of Metallurgical & Chemical Engineering

SIR:—The writer was very much interested in reading the article on "Concentration and Flotation of Lead Ores in Southeastern Missouri," in your issue of July 15, 1916, since he has just returned from an extensive trip through this district.

Under the heading of "Crushing and Grinding" a statement is made to the effect that "the first introduction of the modern ball mill for regrinding is being made at the Rivermines Mill of the St. Joseph Co., where an 8-ft. dia. Marcy mill operated by a 200-hp. motor is being placed." This statement is not quite correct, since a 6-ft. Hardinge ball mill has been in operation at the plant of the Desloge Company since the early part of April, 1916, for the regrinding of their jig middlings. Two further Hardinge ball mills are also being installed in this district at the present time, one, an 8-ft. dia. machine at the plant of the Federal Lead Co. at Flat River, driven by a 125-hp. motor and the other a 6-ft. dia. machine in the Bonne Terre plant of the St. Joseph Lead Co. These machines are all intended to regrind minus 9 mm. and plus 2 mm. jig middlings for table concentration in place of the rolls which have previously been employed for this work.

The Hardinge ball mill at the plant of the Desloge Co. was the first introduction of a modern ball mill of either the conical or cylindrical type in this district and antedated the introduction of the cylindrical mill at the Rivermines mill by some three months.

By-Product Coal Ammonia as a Domestic Nitrate Source

To the Editor of Metallurgical & Chemical Engineering

SIR:—The present unusual interest which is being given to the development of those industries and proc-

esses which are necessary for the production of war munitions and as a means for preparedness has a tendency to cause certain assumptions to become fixed in the public mind as basic facts and which form the starting point for all discussions. This tendency may cause us at this time to take action which will restrict the development of certain of our natural resources rather than assist them. For instance, certain of our scientific authorities are at this moment making the radical assumption that the basis of an independent source of nitric acid lies solely and only in the development of cheap water power.

The object of this short discussion is to call attention primarily to the fact that we have at hand the potential elements of the cheapest electric power and an almost unlimited supply of raw material for nitric acid, and that these elements do not depend upon or concern themselves in the slightest way with the development of water power.

It might be well to consider for a moment the possible sources of the nitric acid supply which our military authorities consider to be the essential element in the manufacture of explosives in case the seas were not open to our commerce.

Outside of the well-known Chile nitrate beds on which we depend at present, there exists three possible sources of nitric acid supply:

First—The electric arc oxidation of atmospheric nitrogen to the nitric oxides and the conversion of these to nitric acid direct. (The Birkeland Eyde and Pauling processes.)

Second—The hydration of atmospheric nitrogen to ammonia in the electric furnace or catalytic process and the subsequent oxidation of the ammonia to nitric acid (The Haber process and more indirectly the cyanamid process).

Third—The oxidation of ammonia formed directly in the coking or gasification of our bituminous fuels to nitric acid by the catalytic process. (The Ostwald process is also the final step under Class 2.)

All these three sources are being utilized by the warring powers in Europe at the present time on a large commercial scale.

The first two processes require a very large input of electric energy and the second requires in addition large quantities of raw material in the form of lime and coke.

The first two processes are receiving at the present moment a vast amount of publicity and it is generally acknowledged that their successful operation depends primarily on the ability to obtain extremely cheap electric power.

It is further being assumed that this cheap electric power can only be obtained from water-power development.

Some further consideration should be given to the third process which has been almost totally neglected in recent discussions. It is a well known fact that bituminous fuels contain an important percentage of organic combined nitrogen in such form that by treatment in processes such as the by-product coke oven the coal gas retort and lastly in the by-product gas producer, considerable quantities of ammonia are generated and recovered as a by-product.

It is not so generally understood, however, that in the by-product gas producer as developed in Europe during the last twenty-odd years approximately 70 per

cent of the available ammonia in the bituminous fuels can be recovered and made available, and that this percentage of ammonia is approximately four times the amount per ton of coal which can be recovered in a modern by-product coke plant or coal-gas plant. These by-product gas producers recover also a considerable amount of tar and generate besides these by-products a fuel gas which is entirely suitable as fuel for industrial furnaces, for the usual steam turbine plant or gas engines.

A complete power-producing unit of this character is, therefore, capable of solving two of our difficulties at the same time. It will furnish cheap electric power to be used in other processes and it will, also, as a by-product, produce a large quantity of ammonia suitable for fertilizer in peace times and convertible to nitric acid in case of war.

Some doubt has been thrown on the commercial practicability of oxidizing coal ammonia to nitric acid by some of our technical experts. There is no question, however, that this problem has been completely solved on a commercial scale in Germany. The writer has the records of a commercial plant which operated steadily for five years before the start of the war using coke-oven ammonia to produce nitric acid.

By the combination, therefore, of a power plant using by-product producers with ammonia oxidation apparatus we have a unit which produces ammonia and the resulting nitric acid together with a very large output of electric energy which may be applied to other industrial uses or to the production of further nitric acid by either of the other processes referred to above. The raw material which is required to produce this ammonia and electric power is bituminous fuel.

It is possible to demonstrate by using the most modern designs which have been adapted to American conditions that power can be generated in a plant of, say, 100,000 hp. capacity at a cost less than \$5 per horsepower per year, including all fixed charges. This is cheaper power than Niagara, of which we hear so much present talk. It has certain unmistakable advantages over Niagara power. Firstly, it is cheaper in first cost of plant. Secondly, it produces large quantities of a nitrate base and fertilizer as a by-product and the main product, either cheap electric current, or a good fuel gas is available for other electrochemical work or more nitric acid production. The obvious economy of this producer gas process lies in the fact that ammonia and tar worth approximately \$3 is recovered in the gasification of one ton of fuel. The cost of this ammonia recovery is less than \$1 per ton of fuel.

As an evidence that these remarks are neither visionary nor premature, attention is called to the fact that the German Government installed a plant of this character two years before the war started, at its central station at Heinitz, Germany. At the time the war started there were approximately eight plants of this kind operating in Germany. England has about forty such. The combined coal capacity of the plants of this type in operation abroad is approximately 2,000,000 tons per year. Japan has also four large plants and is about to build another large one. One of these is owned by the Japanese Government.

While the process is by no means experimental, nevertheless considerable development work has been done in a full-sized plant in this country during the past two years in adapting the foreign designs to American fuels and conditions. This work has demonstrated clearly the large possibilities of the process under our conditions when employing the latest mod-

ern designs. Mine refuse also has been regularly used in this plant; a material which had previously been considered utterly worthless.

The possibilities which lie in locating a by-product producer power plant adjacent to the bituminous coal mines and using the extremely cheap American fuels as a source of cheap electric power have not been appreciated in the recent discussions concerning the development of our water powers and other natural resources. In this respect the by-product producer industry is suffering under the same neglect which overtook the by-product coke industry after the first few failures of the foreign designs which were brought bodily to this country and installed and operated without carefully considering our local conditions and fuel characteristics. For many years the by-product coke industry in Europe enjoyed a rapid development while the industry here remained practically dead. At the present time, however, there is no question of the success of coke production with the recovery of by-products.

The problem of producing fuel gas for power generation with the recovery of tar and ammonia is one which promises to develop with equal rapidity during the next few years. In the opinion of those who have studied its development in Europe it presents no inherent difficulties and the recent demonstrations and development work to adapt same to American conditions have shown that its introduction here on a commercial scale is both practical and profitable.

It is particularly important at this crisis in our national affairs that we give full consideration to all possible means of conserving our natural resources in regard to electric power as well as of ammonia and nitric acid raw materials. It should not be forgotten, therefore, that we are destroying yearly the available ammonia in nearly four hundred million tons of bituminous coal. We recover at present only about 1½ per cent of the available ammonia which might be extracted from such coal by fully developed and well-known methods. In recovering the ammonia from these fuels by the producer gas process one merely converts the fuel value of the coal into fuel gas. This gas can be used in most industrial operations more readily than by burning the coal direct. If only 5 per cent of the available ammonia contained in these fuels which we are destroying were recovered we would have an ammonia base for nitric acid or fertilizer production which would make us entirely independent in peace or war, of foreign importations.

New York City.

The Iron and Steel Market

No increase in activity has occurred in the steel market. Buying by the domestic trade continues very light, while export demand continues at about the proportions obtaining in two or three months past. The dullness in the domestic market is attributable solely to the season of the year, when new commitments are never undertaken in a large way. The pressure for deliveries of material already bought is substantially as heavy as ever.

As noted in the report of a fortnight ago, the dullness in the steel market serves to show the fundamental strength of the situation, as there is no wavering in the matter of prices and no seller is making a special effort to effect sales.

So strong does the market appear that predictions are occasionally made as to a fresh buying movement in the fall, and one of no mean proportions. Two months ago

such a prediction would have been considered visionary by practically all observers.

One element is present to induce buyers more readily to take hold, that being the large export demand. It was this influence that caused the first really aggressive campaign of buying in the domestic market a year ago. For months domestic buyers had been strongly of the opinion that during the war no really strong and active steel market could be developed. Then, in June and July, they modified their views to such an extent as to admit the possibility that export demand might perhaps become so great as to make steel scarce. It was the fear of such a development that caused the first really important buying in the domestic market, and it was months before it was realized that the export movement was not especially heavy, and that it was domestic business that was filling the mills.

Now, however, the export business has become much larger from a tonnage standpoint. Following is a summary of exports of the so-called "tonnage" products, those that are returned by weight in the government statistics, including scrap, pig iron, unfinished steel, finished rolled steel, pipe, wire products, etc.:

	Gross Tons
Monthly average, first half 1915.....	216,000
Monthly average, second half 1915.....	377,000
Monthly average, four months 1916.....	387,000
May, 1916.....	540,549

Export orders placed during the past two or three months suggest that exports during the remainder of the year are likely to be larger rather than smaller than those of May.

Shipments at Higher Prices

The advances in steel prices practically ended in March, and as the mills had been unusually reserved in the matter of booking open contracts the average invoice price of shipments has been approaching the current market level more rapidly than is usually the case in these upward market movements. As a check to such a generalization it may be cited that the estimated shipments of the United States Steel Corporation during the first six months of this year are substantially equal to the unfilled obligations the corporation reported for the close of business in December.

A further evidence that really high priced steel, steel averaging not far from current market prices, with, of course, various exceptions in special cases, is found in the remarkably high earnings reported by the Steel Corporation for the months of May and June. The monthly earnings have been as follows:

January.....	\$18,794,912	April.....	\$25,123,673
February.....	19,196,396	May.....	27,551,899
March.....	22,722,816	June.....	28,147,476
Quarter.....	\$60,713,624	Quarter.....	\$81,126,048

An interesting computation, not accurate, of course, but still quite illuminating, can be made. The corporation's daily shipments are assumed, from various data, to have increased from 47,000 tons daily in January to 51,000 tons daily in June. There were wage advances Feb. 1 and May 1, and the January, May and June earnings are corrected to what would presumably have been earned had the wage rates prevailing from Feb. 1 to May 1 been paid in those months. Finally, deductions are made for estimated profits in ore transportation in April, May and June. With these allowances the apparent profits per ton of steel shipped are computed roughly as follows: January, \$14.30; February, \$16; March, \$17.25; April, \$20.25; May, \$21.15; June, \$21.15. The computation is subject to considerable error, but it is sufficiently close to indicate that the rapid increase in earnings, due to higher realized prices, ended about May 1. Increases in earnings due to higher realized prices will come much more slowly in future. Incidentally, it

may be remarked that the Steel Corporation's earnings increased by more than \$20,000,000 from the first quarter to the second quarter, the third quarter is unlikely to show any material increase over the second. Shipments will be less, on account of hot weather, and the June rate of earnings is quite unlikely to be maintained.

Base prices of finished steel products, for shipment at mill convenience, are strictly maintained, and the market is very strong indeed in that respect. Premiums for early shipment, which decreased materially during the second quarter of the year, have shown, if anything, a slight increasing tendency in the past two or three weeks, plates being easily the leader in this respect, prompt deliveries being a shade higher than 30 days ago. Steel, as steel, is still scarce, and Bessemer is less plentiful, relative to open-hearth, than a month or six weeks ago, there having been fairly large buying by foreign and domestic consumers who set out to obtain open-hearth but contented themselves with Bessemer in order to secure desired deliveries.

Steel production has been materially curtailed by the hot weather of July. Labor is more independent than usual and yields to the influence of hot weather.

New construction work is proceeding very slowly, and the increases in steel making capacity month by month are relatively small, quite below the expectations.

Pig Iron

The pig iron market continues to drag along an uneventful course. There is neither buying pressure nor selling pressure. The buyers represent that they are well covered and have no occasion to take an interest in the market, nor do they admit that there is any prospect of their requirements increasing. The furnaces appear to be well sold up, and are quite content with the rate at which pig iron is being taken out against contract. Thus there appears to be an even balance, except for two possible circumstances. In the case of the foundries there have been labor troubles galore, and in some cases at least these have resulted in pig iron being piled in foundry yards. Should the melt continue to be restricted on account of labor scarcity and strikes the foundries might take somewhat smaller shipments in future, while, on the other hand, if they were able to increase their melt they might buy additional iron. The other circumstance that may affect the pig iron market is the action of the large steel interests. They are endeavoring to bring in new steel-making capacity, and their stocks of pig iron have become very small. There is a possibility of some of the large steel makers buying pig iron in the market, and the balance is now so delicate that in such an event price advances would probably be forced, and after such a long period of practically stationary prices the effect upon regular buyers, who are now indifferent, would probably be electrical.

The Niagara Falls Power Famine

Meeting of the Committee on Foreign Affairs of House of Representatives and the Niagara Falls Board of Trade

At a luncheon-meeting given by the Niagara Falls Board of Trade to the members of the Committee on Foreign Relations of the House of Representatives at the Prospect House, Niagara Falls, N. Y., on July 13, 1916, the electrochemists presented their side of the power question in such a concise and convincing manner that we feel it a duty and pleasure to publish all the speeches in full.

Hon. CYRUS CLINE presided.

The members of the Committee on Foreign Affairs were welcomed to Niagara Falls in a gracious little speech by Mr. W. ACHESON SMITH, general manager of the Acheson Graphite Company, as one of the five men who now rule Niagara Falls under the city-manager form of municipal administration.

After luncheon Chairman Cline opened the formal meeting.

Mr. F. A. J. FITZGERALD, president of the American Electrochemical Society, was the first speaker:

It is very appropriate that something should be said to-day about the chemical industries of Niagara Falls, for it is almost exactly 21 years since the current from the Niagara Falls Power Company's generators was turned into the aluminium pots of the Pittsburgh Reduction Company and the greatest electrochemical center in the world was born.

The aluminium process, the first of these great Niagara Falls industries, was invented by the late Charles M. Hall and a few months later in the same year that master-inventor, Edward G. Acheson, started to manufacture carborundum. This, with the assistance a few years later of Jacobs' alundum, has revolutionized the abrasive industry all over the world. Shortly after the manufacture of carborundum started we had the first plant making Willson's calcium carbide. Then followed the great plants making caustic soda and bleaching lime by the process of Hamilton Young Castner and another great factory using the same inventor's method for the production of sodium. During these years Rossi was carrying on at Niagara Falls his experiments on ferrotitanium which have resulted in one of our most important industries. We have here also thousands of horsepower devoted to the manufacture of other ferroalloys such as ferrosilicon, so absolutely necessary to the production of steel. But it would take altogether too long to attempt mentioning all the developments of American inventive genius and enterprise which have flourished on the fertile soil created by Niagara power.

There is, however, another side of the subject which is by no means so cheerful, for the brilliant prospects of a few years ago are becoming dim. Since the great war broke out public attention has been strongly directed to the manufacture of nitric acid from the air; but, outside of technical circles, very few people know of the pioneer work done on this problem by Bradley and Lovejoy at Niagara Falls. Their work soon showed that for the successful working of the process enormous quantities of cheap power would be required and consequently the enterprise was never brought to a commercial basis. Yet to-day there are less efficient processes than that of Bradley and Lovejoy working in countries where sufficiently large quantities of power can be obtained.

There is a widespread but erroneous belief that the development of the electrochemical industry will spoil the scenic beauty of the Niagara Falls and this undoubtedly seriously threatens the existence of the industry. Again in this relation we hear much about the exploitation of natural resources by private interests and the consequent injury to the public. But as so often happens in cases like this the real interest of the public has not been considered. For this oversight neither the public nor our legislators are to blame simply because those who know better have never taken the trouble to explain to others the relation of Niagara Falls industries to the public at large and how every citizen of the United States is vitally interested in them.

Now, at the eleventh hour, when these industries are facing a serious crisis those who realize what this means

are anxious to devote all their energies to giving the widest publicity to what they know.

Mr. FRANK J. TONE, works manager of the Carborundum Company, spoke of the Niagara electric furnace companies as follows:

In speaking of the electric furnace industries here, I wish to mention very briefly how these industries have originated, what products they make and more especially what an essential part these products have become in the industrial life of this country. Our electric furnace industries comprise aluminum, calcium carbide, carborundum and the artificial abrasives, ferroalloys and artificial graphite. In the first instance these products have all been made possible by Niagara power. Most of them were discovered a few years previous to the development of power here, and in 1895 some of them were struggling along with steam power, some were laboratory processes and some were still laboratory curiosities. When electric power became available here in large quantity and at a reasonable price it became possible to develop these new metallurgical products on a commercial scale and now they have become so indispensable that a failure in the supply would be a calamity to some of the greatest industries of the country.

Take for example the making of steel, the greatest of all American industries. In 1915 we produced 28,000,000 tons of steel in this country and in two-thirds of this there was required ferrosilicon, an absolutely essential element in producing sound castings and sound ingots. At the beginning of the war all the ferrosilicon used in this country was made by Niagara power in plants located both here and on the Canadian side. The Dominion Government at once placed an embargo on the exportation of ferrosilicon to the United States, all of this alloy being required for use in Canada and in Great Britain. This threw the burden of supplying the American market entirely upon the ferrosilicon works at Niagara Falls and caused an acute shortage which still continues. A cessation in the supply of ferrosilicon would shut down every steel mill in America.

Silicon metal is another Niagara product of importance to the steel industry. It is used in making transformer steel for electrical apparatus and greatly reduces the electrical losses. It is saving millions of dollars annually wherever electrical energy is being transformed. It is also used for the generation of hydrogen for dirigible balloons and balloons for military purposes. Every army in Europe to-day is equipped with apparatus for the use of silicon in connection with their observation balloons.

Perhaps the most striking illustration, however, of the dependence of industry on Niagara power is that of high speed steel. This requires in its manufacture the alloys ferrochromium, ferrovanadium and ferrotungsten. All these are products of Niagara power. Before the invention of high speed steel when we used ordinary carbon steel, a metal cutting speed of 15 ft. per minute was commonly employed. Contrast this if you will with what may be seen in any machine shop where a tool of high speed steel running at a red heat at a speed of 40 or 50 ft. per minute is taking off chips $1\frac{1}{2}$ in. wide and $\frac{1}{2}$ in. thick. High speed steel has tripled the capacity of every machine shop in the world and the efficiency of every workman. It has cut to one-third the capital investment in plant required to accomplish a given volume of work. This is due to ferrochromium, a product of Niagara power.

Ferrochromium is also the hardening agent used in making armor plate and armor piercing projectiles. Without it we would be unable to equip a single battleship with protective armor or serve a single coast defence gun with modern projectiles.

The battleship Pennsylvania, our latest dreadnought, has 10,000 tons of armor. This required in its manufacture 300 tons of ferrochromium. That is to say, 12 carloads of a Niagara product has gone into the battleship Pennsylvania, and if the United States is going to embark on a broader naval policy one might ask, "Where is the ferrochromium coming from?" It certainly is not coming from Niagara Falls unless there is a change in the power situation here. I might answer that if things continue as they are we will go to Canada or Norway for ferrochromium for our armor plate.

An armor piercing projectile is an interesting product. Fired at a distance of 8 miles to pierce 12-in. armor plate, it must have an energy of 30,000 full tons or twice the energy of a modern express train running 40 miles per hour. It pierces the plate and passes completely through it without suffering deformation. This is because the point is made of chrome steel produced from ferrochromium, a Niagara Falls product.

Another product that Niagara Falls power has brought

into every day use is a metal aluminium. It was the pioneer industry to use Niagara power and its beginnings were small. Last year the production was 80,000,000 lb. It is used in electrical transmission conductors, cooking utensils and various metallurgical purposes, but perhaps the most important use is as a structural material in aeroplanes and automobiles. The shortage to-day is very acute and is regarded by automobile engineers as little less than a calamity.

Calcium carbide is also a product of great importance to industry. We know it best in the acetylene lighting of towns, isolated buildings, miners' lamps and harbor buoys. However, by far its most important use is in the oxy-acetylene flame for the welding and cutting of metals. In the steel foundry we see an oxy-acetylene flame cutting sprues of castings and replacing 12 men working with the old methods. Several years ago, when the Quebec Bridge collapsed, engineers said that it would require as much labor to remove the wreck as it would to put up a new bridge, but it was found that these huge twisted girders could be cut up very successfully by the use of the oxy-acetylene flame. Without the oxy-acetylene flame the battleship Maine could never have been chopped up and removed from Havana Harbor. When the steamer Eastland turned turtle in the Chicago River it was the oxy-acetylene flame that made it possible to quickly cut a hole in the hull and rescue scores of passengers. It is Niagara Falls power that has given this wonderful tool to industry.

Other important Niagara products are carborundum and alundum, artificial abrasive or grinding materials. They are fundamental elements in the metal-working industries and Niagara Falls has always been the sole seat of the industry in America. At the beginning of the war the supply of the natural abrasives, Turkish and Grecian emery, was entirely cut off and it became necessary for the artificial abrasive manufacturers in the Niagara district to supply the entire demand. This has resulted in an acute scarcity of the product. The shutting off of the supply would have crippled the great metal working industries of the country such as automobiles, locomotives, agricultural implements, electrical machinery, paper-making machinery, flour milling machinery, firearms and all manufactures of steel, iron and brass. For example, take the automobile industry. The perfection of the modern automobile and the interchangeability of its parts have been largely brought about by the development of the modern grinding wheel. Practically every part of the automobile is ground at some stage of its manufacture; crank shafts are roughed and finished with grinding wheels, likewise cam shafts, pistons, cylinders, ball bearings, etc. It is no exaggeration to say that if the automobile manufacturer was now deprived of artificial abrasives and compelled to go back to the grindstone, and at the same time we took away the other products of Niagara power, aluminum, oxy-acetylene welding and high-speed steel, a works that now produce 500 cars per day would be reduced to an output of 100 cars per day with the same plant and same workmen and the cost would be correspondingly increased. In fact, there would be no automobile industry on its present existing lines.

A word in regard to the power situation in the abrasive industry because it is typical of many Niagara industries. The Carborundum Company has a plant with an electrical capacity and a furnace capacity of over 20,000 hp., and all the power it can get to-day is 10,000 hp. for a continuous 24 hr. load. It has therefore constructed a works in France of 7000 hp. capacity and is bringing all the product over here for distribution to the American market. As the situation has become more critical during the past few months it has decided to build a plant across the river in Canada using Niagara power, and this plant is now under construction. Practically the entire output will be brought over for use in the American market.

We are striving to-day to make America industrially self-contained, but while the demand for the products of Niagara power by the great and basic industries of the country is increasing at a very rapid rate, our ability to supply these products is by no means keeping pace with the demand. It does not even remain stationary. Our ability to meet the demand for these essential products of the electric furnace is actually decreasing month by month.

Mr. A. H. HOOKER, technical director of the Hooker Electrochemical Company, in speaking of the Niagara electrolytic industries, addressed the committee as follows:

During your trip in the automobiles on Buffalo Avenue as you turned and came back, the plants farthest up were the Oldbury Electrochemical Company and the Phosphorus Compounds Company, where they are making chlorates

and phosphorus and its compounds, products which are vital to the match industry of the country. Phosphorus also finds an important and irreplaceable use in the metal industry as a deoxidizer and hardener in many non-ferrous alloys, chiefly in the phosphorizing of copper for the manufacture of phosphor bronze used on battleships and for certain bearings on machines. The use of chlorate in gunpowder is also known to all. Next to these plants in line is our own plant, the Hooker Electrochemical Company, to which we have made large additions in the last year; directly across the road is the Niagara Alkali Company. Both plants make caustic soda and chlorine products.

I shall tell you something about some of the uses of these products. For instance, in the paper industry chlorine in the form of "bleaching powder" is used; for every 100 tons of book paper there are 20 tons of bleaching powder used. So you see what a vital product it is in this industry. Then it is an all-important disinfectant. The water in a thousand cities of this country is by the use of "chloride of lime" or calcium hypochlorite, or free chlorine, sterilized to a point where we need no longer have typhoid epidemics. Our own city, Niagara Falls, is a wonderful example of such use. Not long ago Niagara Falls was a typhoid fever plague spot—nothing less—caused by our use of water polluted by the sewage from Buffalo and other cities; but now that is all changed and we have not had a single case of typhoid; no, I won't say a single case, but practically that—since this same chlorine treatment of our water was started. I leave it to your imaginations to see whether or not other cities will not follow our example and use this product for the same purpose until it has become invaluable for the purification of our water supplies. Our own army is now using the same chlorine treatment to avoid the dangers from typhoid which beset our soldiers during the Spanish-American war. In Europe the best preventive of blood poisoning and infection from dirty wounds is reported to be a mixture prepared from "chloride of lime" or "bleaching powder." Without this same "bleaching powder" our cotton dresses and sheeting would no longer be white; our shirts and collars from the laundry would be a dirty yellow; and, what is worse, a serious menace to health would result through lack of disinfection. Also, white cotton batting, bleached shellac, chloroform for surgical operations, even the disinfection of our garbage and sinks, call for chlorine in the form of "bleach." This same chlorine is used for the production of carbon tetrachloride, which in the form of "pyrene" has become a household necessity as a fire extinguisher.

Chlorine is used to-day not only in the form of "chloride of lime" for bleaching, for the bleaching of paper and textiles, but it also enters into a wide number of products that we do not ordinarily think of. For instance, a large addition recently made to our plant has been for the chlorination of benzol. Chlorbenzol is one of the coal-tar intermediates which this country has never before produced. Prior to one year ago I believe there had not been 200 lb. of chlorbenzol made in this country—I think we made something like this amount at that time—but to-day there is being made many thousand times that amount right straight along.

By passing chlorine gas into benzol or toluol there is formed hydrochloric acid and chlorbenzol or chlortoluol and the latter products can then be used to form picric acid, benzoic and trinitrotoluol, etc.; it is equally desirable for the production of sulphur black used for a dye, for instance of your socks, and for the production of carmine reds that are used on our automobiles and cars and agricultural implements, and hundreds of other directions in the manufacture of dyes. So for explosives in time of war or for dyestuffs in time of peace, we are getting ready to be of service.

These industries which we have developed and those which we are starting now, for which the country feels such an urgent need, we want to keep in this country, and want to keep them here permanently. I do not see how we are going to continue with the power situation as it stands to-day. We have taken the risk of putting a large sum of money into these new industries, and we have got to grow, or else, as with everything else, we shall reach a point of stagnation. That growth will require more power, not less, as times goes on, because we have got to have additional products; and so it is all down the line, the same proposition occurring all through the electrochemical industries.

Take caustic soda, so vital to the soap industry, so vital to the manufacture of artificial silk, the refining of oils and the mercerizing of cotton, the manufacture of dyes, explosives, cleaning of metals, etc., I believe you all know what household lye is, what caustic soda is, and what a vital part it plays in our many industries and how important it is

to our whole nation. The two plants named above and the pioneer company, The Castner Electrolytic Alkali Company, which make caustic as well as chlorine compounds, are absolutely dependent upon Niagara Falls power, and turn out a great deal of the caustic soda produced in this country.

When you get down a little farther on your trip you came to the plant of the Niagara Electro Chemical Company, making metallic sodium, using this same caustic soda produced at Niagara Falls. This metallic sodium is converted into cyanide, and upon this product depends your gold and silver mining industries, the plating industry, etc. The country being cut off from the supplies of German sodium cyanide, it looked for a time as if our mining industries would be seriously affected, but with enlargements and increases in our own production we have been almost able to hold our end and keep up with the necessities. A great deal of cyanide is used in killing the enemies of citrus trees, and California citrus fruit crops are dependent somewhat upon cyanide made from Niagara power.

From sodium is made sodium peroxide from which again is made hydrogen peroxide, which is used for bleaching and which also is used in the household. From sodium peroxide is made a material which is used as a source of purifying air in submarines, in life-saving work in mines, hospitals, etc. I speak only of these as a few of the different electrochemical products we are making here at Niagara Falls, and their relation—their vital relation—to the industries of the country.

I well remember a little situation that came up to me in December as showing this condition. A cotton batting mill had neglected to make contract for bleaching powder. They possibly thought it would come down in price, or else neglected it, thinking it not a very important item in dollars and cents, as the price of the product was cheap—a little over a cent a pound. However, they had no contract and came to us in December and wanted to know if we could not supply them with "chloride of lime" to keep them going. I said that I did not know, but would take the matter up with our New York sales office. I telephoned to our New York office, but our company could not supply them, but they did make some arrangement whereby they were able to keep this plant running. The situation was simply this, that the whole country was absolutely swept clear of these chlorine products and they could not be got for love nor money.

I might cite another instance: One of our largest stockholders was using a small amount of bleaching powder. He wanted to buy some small amount of bleaching powder from us, but had no contract and our supply was exhausted. We tried to get some bleaching powder for him and we had to pay \$250 a ton because of the shortage of these products, although we were selling the bulk of our supply for perhaps \$25 per ton.

This simply goes to show the effect of the shortage and the necessity for these products that are made in Niagara Falls, the center of the chlorine industry of the world, and it also shows how vital these products are to the full, economic life of the country. Still it seems like a little thing which you hardly ever think of. So when we have started plants here, if we cannot get the water power to develop them to that stage which is necessary to keep up with the normal demands of the country, or to meet such special contingencies as when the country was shut off from foreign supply by the war, it simply finds every one of these industries in a position where it has to look for another source of power. As Mr. Tone has said, we will have to develop a plant in France or Canada or elsewhere. We have got to grow. We cannot stand still. We have got to have more electrical power, or else we simply lose what we have had in America—the greatest center of the electrochemical industry in the world; and this is a great deal more of an asset to the country than the dye industry has been to Germany. Simply for lack of power we are letting our industries scatter, here and there, over to Canada and elsewhere, instead of keeping them for the benefit of our own country. It certainly seems that we should keep our industries right here, and that some means should be devised to utilize the maximum power from the Falls.

We cannot stand still; we have got to grow.

Mr. I. R. EDMANDS, consulting engineer of the Union Carbide Company, was the next speaker and made a positive suggestion as to how to go about in order to get a new international agreement:

I believe you will all agree that the power that has been developed at Niagara has been a tremendous help to the people of this country and Canada, by increasing domestic and civic convenience and aiding industrial development.

I believe you will all agree that all the 20,000 cu. ft. per second of the flow of the Niagara River allowed us by treaty between United States and Great Britain, should be used and also that the 4400 cu. ft. of this amount not now being used is a big mistake, as it is a wasted available and desired resource of this country.

I believe you will all agree that every cubic foot of water in the Niagara River that is not needed to maintain the scenic beauty and grandeur of the falls should be put to useful work.

The big question is how many cubic feet of water can be diverted from the falls without diminishing their beauty and grandeur. After several years of careful measurement and observation of some able government engineers, they decided that 25 per cent of the entire water of this river could be diverted without detriment, and on their reports the amounts set forth in the present treaty were determined. Over 21 per cent of the normal flow of the river is now being used and no appreciable diminishing of their beauty is noticeable, and it is very evident that much more can be used without detriment.

An eminent engineer living at Niagara, who has made a careful study of the effect of flow condition on the scenic feature, believes that by proper placing of submerged dams above the falls, 50 per cent of the normal flow can be diverted without detriment to the scenic beauty. If he is right, what a crime is being perpetuated on our natural resources! An additional 25 per cent of the flow of Niagara River at the falls represents about one million horsepower, or, if developed by steam, the use of about six and one-half million tons of coal per year. Shall we continue to let this water run to waste?

Strenuous efforts should be made by our government to help get this water in use, instead of the present methods of restricting it.

If the use of water in excess of that allowed by the present treaty is contemplated, there are many existing interests which should be considered.

But who will take the initiative?

As a suggestion, why shouldn't Congress arrange for the invitation of a commission to investigate the further diversion and use of water from the Falls to the full amount possible, still maintaining the scenic beauty and grandeur and without harm to navigation; then have it make recommendations to the United States and Canada for further action.

This commission could be made up of representatives of the various interests involved, such as one from the Dominion of Canada engineers and one from the United States Government engineers, one from Canada and one from the United States representing the public interest in the scenic grandeur of the Falls, one from each country representing the existing power companies, one from each country representing industries using Niagara power and one from each country representing navigation interests, also one from each country of the members of the International Joint Commission.

The Commissioners should be empowered by the interests they represent to energetically spend as much time and money as is necessary to obtain proper information and engineering data required, on which to base their recommendation to the two governments.

I wish to submit this for your consideration.

Mr. F. A. LIDBURY, manager of the Oldbury Electrochemical Company and a past president of the American Electrochemical Society, spoke as follows:

Our guests to-day may have noticed that the speeches and in general the talks they have heard possibly differ in one important respect from those they are accustomed to hear when they visit specific localities on specific problems. I think we can claim there has been nothing local, nothing sectional, presented to-day. We have tried to present this as a national matter, a matter of extreme national importance.

There is one very difficult problem in connection with the power situation at Niagara Falls, and that is the problem of getting into the minds of the people at large a thorough understanding of what the power development at Niagara Falls means and has meant to them. There are problems of considerable importance, analogous problems, where this difficulty does not arise, and we have all seen in the last year or so, the problem of the dye industry discussed with a great deal of intelligence, simply because the average individual, the everyday member of the public, understands what the production of dyes in this country means to him and what it means to him to do without it; but it is extremely difficult to get a layman to understand what the electrochemical production of this city means to him.

though the importance of that production is, I venture to say, several thousand times the importance of the dye stuff industry in this country.

Now, why is that? It is because he is only affected indirectly. Though in everything he does, in every activity he indulges in, from the time he gets up in the morning until he goes to bed, he is enormously benefited by the electrochemical production of this city. He does not know this because he does not eat bleach, and he does not wear phosphorus, and he is only reached indirectly through a number of stages, and he does not know what these stages are.

An attempt has been made by the papers which have been circulated amongst you and the speeches which you have heard to give you a few—and only a few—of the most important lines along which the electrochemical industry has directly and importantly influenced the industries of this country; but it must be realized that a phenomenon that has been one of the most significant things in industry in the last fifteen years cannot be discussed in fifteen minutes. We realized, we electrochemists have come to understand that not the power companies, but we, are the crucial point in this situation, and it is up to us, and it is a matter of duty for us to get before the people and their representatives exactly what we do and what we need. Now, that is what we are trying to do, and it is very difficult; but there is one thing we have to say to you gentlemen, and that is that the American Electrochemical Society, of which the present president and two past presidents are before you to-day, is most anxious to get before you all the information on this subject that it can, and it stands ready to send out representatives at any time to Washington to give you all the information at their disposal at any time you want to send for them. It is impossible to do it in a few minutes' conversation, but we do feel that we have said enough to-day, and these papers that you have got, if you will read them, will show you enough to indicate that this is really not a matter of secondary, but a matter of primary, importance to the people of this country.

I referred to the dye stuff situation and to the general appreciation of the results which will follow any extreme shortage of dye stuffs. The results which would follow an extreme shortage of the electrochemical products made in this town are something that no man here could describe. They would have to be experienced to be understood. The mildest way in which I can put the matter to you gentlemen is this: That if it had not been for the existence of these industries in this town, in the last two years, instead of this country having had an industrial boom, it would have had one of the greatest industrial depressions it ever has experienced. You have only to take what Mr. Tone said in regard to the steel industry to understand what would have been involved.

The electrochemical industry in this country is something of which we ought to be extremely proud. We hear a great deal about Europe being ahead of this country in chemical industries and similar lines, but there is one branch of the chemical industry in which this country has never had to take a back seat to Europe, and that is the electrochemical industry. As has been pointed out, this town is the chief electrochemical center of the world, and in fact some of the most important electrochemical developments were born here. This is particularly true of those industries which have had the widest and most important influence upon industries in general.

Now, we are not only proud of this development in general, but we are proud—and we have a right to be proud—of the resources and energy with which the electrochemical industries of this country, and specifically of this town, have, under conditions of extreme difficulty, in certain respects, come to meet the situation in the way of increased demands or the substitution of one article for another, that has taken place since the war began. It would take too long to describe this, to explain in detail what has been done; but let me refer to just one specific case which involved throwing over one industry in order to bring up the production of ferro-silicon to a point where it could be of considerable assistance to the steel makers, deprived of foreign production.

The one thing I want to bring to your attention is what the present conditions are and what the outlook is. Ever since power restriction measures came into effect, there has been noticed a tendency, which recently has resulted in an acute condition, to shortage of power on the American side of the border here, and increasing prices, and greater stringency in contract conditions. The vital requirement of the electrochemical industry is abundant power and cheap power. *Dear power is no good to it.* As a result of these conditions, which started to show themselves immediately the power-restricting measures took effect, there was a tendency to the migration of plants which either originally

began operations here or which would have naturally commenced operations here, to other localities; and I want to specifically call your attention to the fact that the majority of those migrated and the most important of them have been to other countries.

As early as 1907 the first fixed nitrogen plant on this continent was projected. That was the American Cyanamid Company. After carefully looking around and seeing what could be done in the way of power sites in the United States, they decided to locate on the Canadian side of the border, just over the river here, and are to-day consuming something over 27,000 hp. in the manufacture of cyanamid, the market for which is entirely in the United States. The two companies which have revolutionized the abrasive industry have found it necessary to move the greater portion of their furnace operations to Canada, and in one case to France. Recently we have seen the Union Carbide Company erecting a plant to consume 100,000 hp. in Norway, and although it is not yet known where the products is destined for, the principal outlet, it is generally understood, will be in this country.

We can only judge the future by the past and by what we see going on before us at present. What we see to-day is a tendency for these industries to leave this locality because of the lack of power, and to go, not to other parts of this country, but to other countries. Now, why is that? Outside of the power that has been developed here and that can be developed here, there are practically no water powers which offer sufficiently favorable conditions, or which show any prospect of offering sufficiently favorable conditions, for these industries; and there is a very good reason for that. There are lots of water power in this country, and I dare say there are lots of power which can be developed cheaply. Most of it is in the West. Now, the electrochemical products which consume this power have to be transported from one section to another. You can carry them just so far economically, and no farther; and it happens that the consumptive outlet for the majority of the products that are made in Niagara Falls, is in the manufacturing districts of the East. That is, of course, natural because these products are fundamentally important ingredients of the products of the most important industries of the country; consequently, to locate out West is to put a prohibitive transportation cost on the materials; in fact, calculations show that for the purpose of supplying the Eastern markets, the majority of the processes now at the Falls would have to get the power on the Western coast, not only for nothing, but would have to get as much as a bonus as they have to pay for power here!

So if industries move to other parts of the country, they have to go to localities from which they can transport their products cheaply to the manufacturing centers of the East; hence, their location in Canada, particularly those portions of Canada which are near the border here, and which have water transportation, and their location in places such as Norway, from which water transportation is cheap and easy to the Eastern seaboard of the United States. Bad as power conditions now are here, they are likely to become worse. The Dominion Government has reduced the amount of power for which Canadian export permits are given and has served notice of its intention to reduce the exported quantities yearly at a rate which will bring exportation to a complete stop in the course of six or seven years. As at least one-third of the Niagara power used in the United States has been imported from Canada, we are faced with a further curtailment of our already restricted operations. Unless immediate and substantial relief is given, the already insufficient output of our electrochemical plants will be seriously and steadily reduced.

Now, gentlemen, here is the question that we have got to face. Are we going to utilize our natural resources in this country to permit of the further normal development of these industries, which are of fundamental importance to every one of us, or are we going to close our eyes and let things take their course and see these industries gradually expatriate themselves? We have our choice. There is no third way. We have got to make up our minds that we have either got to develop these industries in this country or see them go abroad. It is easy to keep them. All we have got to do is to utilize, instead of allowing to go to waste, those natural resources which have been given to us and which cost us nothing. I think enough has been said to-day to give you an idea of what the frightful consequences may be if such another dislocation of the world's trade comes—if we get into a war ourselves, or if other nations going to war dislocate the world's trade—if we have allowed these industries which are so fundamentally important to grow up, not where they were born and where they ought to be, but in other countries. That is the proposition which faces us.

Now, I do not think that there is any consideration which

is more important in this regard than an answer to the question so frequently put: What has the country got for the alleged spoilage and destruction of the scenic beauty of Niagara, this, that and the other thing that the alleged vandals have done at Niagara Falls? That answer is simple, plain and emphatic. All of you gentlemen know, and know thoroughly well, the effect of the scientific contributions to industry in the last fifteen or twenty years. You know thoroughly well that by those contributions the productive power of each individual in this country has been enormously increased. If you analyse the nature of these improvements, taking the mechanical industries, for instance, which this country is particularly ahead in, and you find that the ability of one man to produce to-day what several men produced before is due—what to? To the contribution of the electrochemical industry to tool steels and to the technique and materials of grinding. The same thing—dependence on the products of Niagara power is true in practically all the industries which have so enormously been improved in the last twenty years, and whose improvements by adding so greatly to the productive power of the individual, have enabled every man in the country to obtain a better and richer existence. That, gentlemen, is our answer to the question: What have you vandals done with Niagara Falls?

Dr. EDWARD ACHESON, the world-famous inventor of carborundum and artificial graphite, was the last speaker. His speech deserves to be called a classic:

Mr. Chairman and Gentlemen of the Foreign Affairs Committee of the House of Representatives:—I understand the purpose of your present visit to Niagara Falls is to give you an opportunity to form a clear and accurate judgment for or against the advisability of permitting a further diversion of water from the Niagara River for power purposes, and, further, its bearing upon the international relations between the United States and Canada.

I have been honored with an invitation to address you, and it is with great pleasure I grasp the opportunity to place before you a few facts which, I hope, you will consider of sufficient importance to bear weight in the formation of your decision.

With your kind permission, I will give you a brief glance at my own activities in and about Niagara Falls, and the results I have been able to accomplish, my excuse for presenting my own affairs to you being that I know them better than my neighbors. There are, however, many other manufacturers who could advance equally strong arguments as those I am about to place before you.

In 1894 I was located in Monongahela City, in the very heart of the bituminous coal fields of Pennsylvania. I was operating a small plant manufacturing carborundum, the production during that year amounting to 52,190 lb. The electrical power for the operation of the furnace, in which carborundum was produced, cost too much money to permit of the material being sold for general grinding purposes.

The first electric power plant erected at Niagara Falls was approaching completion. I came to this city and contracted for 1000 electrical horsepower, built a plant, and during the year 1896 the production of carborundum jumped up to 1,100,000 lb. During the following years the business grew until, during 1913, the production amounted to 20,033,000 lb. Since 1913, the business has shown considerable fluctuation, having dropped to 16,410,100 lb. in 1915, but during the present year—1916—it is running at the rate of 22,433,600 lb., this being the maximum possible production of the plant under the present curtailed condition of power production.

While you will notice that the production in 1916 shows an increase of 38 per cent over 1915, during this year the orders have been coming in to the Carborundum Company at such a rate as to represent an increase of 120 per cent over that of 1915. Notwithstanding these facts, the company has not increased the price of its goods.

It will not be necessary for me to comment upon the great value of this grinding material in the manufacturing world, it now being practically a necessity in many lines of manufacture.

My second venture in commercial manufacture at Niagara occurred in 1900, 16 years ago. It consisted of the manufacture of artificial graphite. The development of this new business has been as follows:

In 1900 the production amounted to 860,750 lb. The following year it had jumped to 2,500,000 lb., and in 1913 it was 13,633,342 lb. This business, you will notice, was developed before the European war had taken form; hence, it had not been influenced by these world disturbances.

Since the beginning of this present year, 1916, the orders for graphite received by the Acheson Graphite Company

have been at the rate of approximately 50,000,000 lb. per year. The company's present plant has a maximum capacity of 40,000,000 lb. per year; while owing to the unfortunate curtailment of power production, only sufficient power can be obtained to produce approximately 20,000,000 lb., and the company faces the further unfortunate condition of possibly being reduced to two-thirds its present output, or 14,000,000 lb., by reason of the Canadian Government having called for a large amount of power now being utilized in the United States.

Let us more closely examine these orders for 50,000,000 lb. of artificial graphite. They are for a material that did not exist 16 years ago. The coming into being of this material has permitted the creation of vast enterprises previously impossible. For instance, as an example, we will take the manufacture of caustic, bleach and chlorine, all important to our present-day life. Competent authorities have stated that their efficient manufacture would not be possible did the artificial graphite not exist. The existence of this Niagara-made graphite has been of incalculable value in hastening the liberation of the United States from the necessity of buying foreign-made products essential to our welfare and growth.

Alongside of and coincident with the growth of these domestic values, is the fact that no less than 29 per cent of this year's business of the Acheson Graphite Company is export trade. Further, these orders from abroad would have been vastly greater had it been possible to fill orders that could be had for the mere asking, and this is happening at the very time Norway, with her great water powers, is becoming restless and shows signs of wishing to enter the world's market with an artificial graphite.

Is it not worth while caring for this export trade? We are at this moment witnessing a great movement of the American manufacturing world towards the creation of a vast export trade. The Government is taking a friendly interest in this movement. Are these Niagara Falls interests too small to be taken into account?

You are, perhaps, thinking and may say I am an interested party, and am only hoping to advance my own interests, but it is possible you may not think so badly of me when I tell you the Acheson Graphite Company has not advanced its selling price one cent since this on-rush of orders. No advantage has been taken of the present great demands for its products.

My purpose in giving you statistics regarding these enterprises is not with the hope of your rendering me assistance to advance my own interests, except as they may be advanced with others. I am presenting them to illustrate what may be done with Niagara Falls power in furthering the interests of our country at large. Many of the products produced in this city are absolutely essential to the successful operation of industries in cities and towns far removed from Niagara Falls.

You may say this is all very good, but why not manufacture these materials somewhere else and preserve the Falls? This brings us to the very heart of this whole matter. Previous speakers have already answered this question better than I am prepared to do. This subject is, however, very much greater than the simple matter of supplying more power and greater facilities to the factories of Niagara Falls. It is nation-wide in importance. You, as a Committee of the National Congress, have a duty to perform and a great responsibility rests upon you.

While you are with us, you will not fail to be impressed with the fact that this is a novel industrial community. Niagara Falls is no longer the pleasure resort of former years. The scenic beauty of the Falls is still with us, but the true value of the Falls and this community, in so far as the country at large is concerned, consists in the vast quantities of manufactured products distributed throughout the world from our local factories, many of which were only made possible of commercial production by the generation of electricity through the diversion of water from the Niagara, and in the invisible, vibrating current of power sent out on radiating threads of copper to cities, towns, and villages within a radius of 100 and more miles. Many of the factories located here on account of the power being cheaper. They have grown to large magnitude, and it is not an easy matter to move them to other localities.

I wish I had the gift of ready language, that I might better impress you with what appears to me to be your opportunity to use your great influence and directing power in bringing about a movement which would be of incalculable benefit to our entire country, and more particularly to our posterity. Would that I might make one small remark that would cause you to depart from what, to me, seems a wicked course—the failure to properly use our great natural resources. We are at the present moment within hearing of the roar of one of the most stupendous forces in the

world. Magnificent and grand from the scenic point of view it certainly is, but to me it would be much grander and more impressive were a large portion of this vast power being utilized for the present and future welfare of man.

I consider it a veritable crime against our posterity to preserve this great natural, inexhaustible resource in its entirety, or as it now is, for reason of its scenic beauty while we at the same time press forward to the exhaustion of the coal deposits of our country.

We are advised our coal supply will be exhausted in another century. Certainly a goodly time, but still not great as we measure the life of nations. There is nothing visionary or fanciful about this early exhaustion of our coal supply. True, we are told of immense coal fields in Alaska, but one cannot readily imagine the factories of New York, Pennsylvania, Ohio, or, in fact, any of the States being supplied from these deposits in the frozen North. Let me impress upon you the fact that a century is not a long period. Three generations will more than cover it. An instance in my own family will well illustrate this. Among the treasures of the family is an invitation from President Washington to one of my grandfathers to dine with him, my grandfather at that time being a member of the Pennsylvania Legislature, and this was more than a century ago. Our own grandchildren may witness the practical exhaustion of our coal if no steps are taken to conserve it.

I have here a few statistics coming from the U. S. Geological Survey: The production of anthracite coal in 1913 was 91,524,927 metric tons. Compare these figures with the production in 1820, which I find was no more than 365 tons, and this was two years after the birth of my father. Here are figures on the production of bituminous coal in the United States: In 1895 it amounted to 124,627,000 metric tons. In 1900 it had increased to 191,256,000 tons, and in 1913 it had jumped to the great figure of 478,523,000 metric tons. You will not find it difficult to see the exhaustion of the coal deposits a century hence.

Perhaps you are not interested in the welfare of the people who will live a century hence, but I assure you that if those people find that a great natural, inexhaustible resource for power, as is the Falls of Niagara, has been preserved to them on account of its scenic beauty, while at the same time the country has been denuded of its coal supply to produce power, these far-away people will be very, very much interested in what you and all of us, of this present generation, have been doing. Unless we have already done so, they will find themselves under the necessity of diverting the water from the river for power purposes; hence *they will have neither coal, which we will have used, nor scenic beauty, which we are trying to preserve.*

In closing, gentlemen, permit me to leave with you the question, "*What is the true, the real conservation of our natural resources? Is it not the full and economic use of the inexhaustible for the preservation of the exhaustible?*"

The Coal-tar Dye Industry, Past, Present and Future*

BY BERNHARD C. HESSE

For the past twenty years or thereabouts the United States has had within its borders a supply of coal-tar materials of suitable quality and in sufficient amount to produce all of its own requirements of coal-tar dyes if it so chose to use them; for the same period of time it has had domestic access to substantially all the needful other or auxiliary chemicals, except sodium nitrate, in which respect it was dependent upon Chile, and in that regard it was in the same position as practically every other nation; to-day we are in most favorable position in these respects. So far as men, experience and equipment are concerned we are now in better condition than ever before.

In the early days of the coal-tar industry, Belgium, France, and Great Britain had the largest domestic supplies of coal tar and other materials, whereas Germany was not so situated, but was dependent upon these three countries for the major portion of these materials. The coal-tar dye industry was started in England and France fully four years before it was

started in Germany; within the first fourteen years of its life, i.e. by 1874, the German coal-tar dye industry made 90 per cent of the coal-tar dyes then consumed in the world.

From the comparatively small number of dyes which constituted the coal-tar dye industry of 1874, say 50 different dyes, this industry has now grown to more than 900 different dyes, involving more than 300 other chemical products, themselves not dyes, but needful in the making of the dyes proper. The activities that led to the development of the dye industry brought about with them phenomenal development in synthetic medicinal, and pharmaceutical products, synthetic perfumes, photographic chemicals, explosives, disinfectants, and means of scientific study and investigation which were not foreseeable a half century ago. Collateral thereto, but none the less important, the technique, information, and point of view so evolved has had a mighty and stimulating effect upon many other branches of chemical-industrial endeavor all outside coal-tar chemistry. Few, if any, chemical activities have been so catholic in their fields of endeavor and so all-pervading in their effects.

Fifty years ago the commercial future of the coal-tar dye industry seemed limited; its possibilities, direct and indirect, did not appeal with any great force to any but the Germans; the industry as it stands to-day is a monument to constructive imagination, a willingness to make and market small amounts, dogged persistence, and the very perfection of salesmanship and operating organization. With but one exception, alizarin, the whole industry must then have seemed as though it would never outgrow the "pot and kettle" stage, that is, manufacture in small units—a "toy" industry, in other words.

In 1913, Germany had twenty-two going concerns making coal-tar dyes; these are the survivors among thirty-nine concerns, of which eleven were abandoned and six were absorbed.

The latest figures available for Germany's export business in normal times are those for 1913; in that year Germany exported 120,000 short tons of dyes having a declared export value of \$51,640,000, or \$430 per ton, or 21.5c. per lb. In the same year Germany exported intermediates to the extent of 22,000 short tons, of a declared export value of \$4,310,000, or \$196 per short ton, or 9.8c. per lb.

In the mass, these are stupendous figures, totaling 142,000 short tons and \$55,950,000, or an average value of \$394 per ton, or 19.5c. per lb. On closer inspection it will be found that for the more than 1200 things that have to be made, this means an average of not more than 118 tons per year, or \$46,625 per year per product for the entire world outside of Germany; at 300 days per year this means on the average not more than 790 lbs., or \$155 per day per product, for the entire world outside of Germany.

The dividends declared and distributed in 1912 by 21 of the German coal-tar dye manufacturers amounted to \$11,600,000. The 1913 dividends were about the same as those for 1912. Of the twenty-two plants of 1913, one declared no dividend and four sustained a loss amounting to about 8 per cent of their capitalization. Per product, these 1912 distributed dividends amount to not more than \$9,700, and these dividends included whatever of profits these concerns made as distributors and makers of their wares, including heavy chemicals, dyes, intermediates, photographic chemicals, synthetic medicinals and pharmaceuticals, explosives, and the like, all inclusive of Germany's own consumption of all these articles. If the German consumption be taken at twice the United States importation in 1913, this makes Ger-

*An address delivered on July 25, 1914, at the Mid-Year Meeting, National Association of Dye and Pigment Manufacturers.

many's total production in 1913 about \$78,000,000; \$11,600,000 in dividends means not more than one dollar in dividends on each \$6.72 of turnover, or not more than 15 per cent on the turnover.

If proper allowance be made for the large individual articles of consumption, the average annual value, output, and profit for the remaining things becomes very much less than above given, and perhaps only 60 per cent of the above average figures, say to 475 lb. or \$90 per day gross per product for all the world outside of Germany.

At \$15,000,000 for the manufacturers' value of all coal-tar dyes consumed in the United States in normal times—and this is a very liberal figure—this means 15c. per year for each of the 100,000,000 inhabitants of this country; for each person in this country to average a consumption of 1c. for each of the present-day 1200 dyes and things needful in making these dyes—i. e., \$12—would take 80 years.

From the point of view of average individual annual tonnages, gross receipts, distributed dividends, or individual personal consumption, there is firm ground for the opinion that even to-day the coal-tar dye industry, big as it is in the mass, is still, in great measure, a "pot and kettle" affair, a "toy" industry, or a "department-store" aggregation of many small units, and that in mercantile reality and in total effect it is just about a "one-nation" business.

In 1913 there were probably not over 40,000 people all told engaged, in the whole world, in the manufacture of coal-tar dyes and of the chemicals needed therefor, apart from making and distilling coal-tar in itself. The entire indigo consumption of the world, which is the largest single item in the whole business, probably can be produced with not more than 1500 men all told. Taking our own total consumption of coal-tar dyes of all kinds as one-seventh of the world's total, 6000 people could reasonably be expected to be the maximum number needed for its production. In 1914, our railroads hauled 1,000,000,000 tons of freight; our dye consumption is about 30,000 tons per year; to make these here would probably not add 60,000 tons to the country's freight haulage, or 0.006 per cent. If we made all and the whole of our own dyes, that would diminish our total national merchandise import business by about 0.5 per cent. Assuming the dividends to be apportioned as above, this would mean about \$1,660,000 of added dividends.

So, from the point of view of added labor, freight haulage, diminution of our foreign business, and added dividends, if we made all our own dyes within the country the project does not seem to be a strikingly alluring one from a national outlook.

Among all the branches of the chemical industry of Germany, the coal-tar dye industry is the greatest of dividend payers, paying ten points more in dividends than any other branch. It sells its products in thirty-three countries outside of Germany, and therefore has its eggs distributed among many different baskets.

In any plans we may make for bringing about our independence of any foreign country for coal-tar dyes, medicinals, and other useful like products, we must take all the foregoing facts and deductions into account, and provide for them and their consequences so far as we can reasonably foresee them.

Why should we be thus independent? In the tariff revision of 1883, dependence upon other countries was avowedly, eagerly and deliberately advocated and accepted, among other reasons given being that we could never build up the coal-tar dye industry here, and that the import duty raised the price of

red-flannel shirts 25c. per dozen and the price of an average-sized rag carpet 3 or 4c. In 1908 there were seventeen New England cotton establishments protesting collectively against any tariff increase, because that would increase the cost of manufacturing colored cotton goods in the United States and the price to the consumer in the United States; and in the case of export trade, an advance in the cost of any of their raw materials adds to their burdens and minimizes their opportunity to compete with foreign cotton manufacturers in foreign markets.

In the 1913 tariff revision, southern cotton mills took substantially the same position. In the record of the hearings on the Hill bill, held Jan. 14 and 15, 1916, some of the seventeen signers of 1908 reversed themselves either in writing or orally. Those who have so reversed themselves represent about one-third of the total labor, power, and textile-machinery capacity of the seventeen, and probably the same proportion of the total capital. Since then others may have reversed themselves, but, if so, that fact has escaped me.

Thus, from 1883 to 1913, coal-tar dyes were regarded as raw materials, and as such they should be free, or taxed but little. Whatever import duty was assessed during that period of time did not in any way encourage or foster an American coal-tar dye industry and did not interfere with our avowed purpose to be dependent upon others in this regard; all this in the face of continued, repeated, and elaborate protests against such a course by those then engaged in making dyes in this country. The probable effect of a European war upon our industries using foreign-made dyes was discussed in July, 1882, as follows: "These goods are made not only in England, but in Germany, and if the worst comes to the worst, and we were cut off from our European supplies, we could fall back on the vegetable dyes that came from South and Central America before aniline dyes were invented."

The 1883 tariff cut closed many of the then existing nine American coal-tar dye plants; to some of the individuals it meant ruin. If, as a result of the present-day cry for re-establishment of this industry a new tariff is enacted and men for that reason engage in this venture, the nation must keep faith and its implied covenant, and not leave these men in the lurch; we must never backslide merely because we then find the actual cost higher than in our present state of mind we believe it will be or think we are prepared to pay. Let us be absolutely clear in our own minds and sure of ourselves. If we decide to go forward—never let us turn back.

Ever since 1883 a specific tax has not been assessed; an advalorem duty and ranging from 25 to 35 per cent, now 30 per cent, and that on a part only, not all dyes made from coal tar. As a matter of fact, we have not had a real domestic coal-tar dye industry—merely an assembling industry; that is about all the tariff can be said to have effected.

In the year 1913, Germany sent us, in round numbers, \$7,300,000 of so-called aniline dyes dutiable at 30 per cent; \$2,800,000 of alizarin and anthracene dyes and indigo, not dutiable; and \$1,086,300 of intermediates, dutiable at 10 per cent. These are the rates of the present Underwood tariff, effective October 3, 1913.

Taking these figures and rates as a basis, the total revenue thus assessable and collectible would amount to \$2,298,632; under the Hill bill provisions this would have been \$6,908,648; and under the Kitchin bill provisions this would amount to \$4,999,084; the increases over the Underwood tariff being for the Hill bill \$4,610,016, and for the Kitchin bill \$2,700,452; that is, where the Hill bill contemplates adding \$1.00 the

Kitchin bill contemplates adding 59c. In other words, where Underwood adds \$1.00 to the export value the Hill bill adds \$3.00 and the Kitchin bill \$2.18, assuming for the purpose of this comparison that the duty imposed will appear entirely as added cost to the consumer, which may or may not be the case.

We know that the Underwood dollar did not create a dye industry. We are led to believe by informed persons, acting upon honor and entirely disinterestedly, that the Hill bill's \$3.00 will probably create a complete self-contained and self-sustaining industry in this country, which will make not only coal-tar dyes and explosives, but also all the many other things obtainable from coal tar and other like materials, and that anything less than that is not likely to lead to any substantial industry. With this view the most experienced domestic coal-tar dye makers agree.

The Kitchin bill proceeds from the admission and premise that the Underwood and all like dollars created no industry to the conclusion that \$2.18 will create a complete self-contained and self-sustaining industry in this country. We know that the Underwood dollar, and all similar preceding dollars, might just as well have been thrown into the sea for all the real domestic industry they created; the Kitchin bill's \$2.18 may merely be throwing good money after bad; we are told that the Hill bill's \$3.00 may be the same, but not probably. That is the dollars-and-cents view of the proposed legislation at Washington.

Again, we are similarly told that protection in order to protect this industry must protect it all the way round. The Hill bill does that; the Kitchin bill does not. If you were building a high board fence round your vegetable garden to keep your neighbors' chickens out, would you build three-quarters of the fence so that it went well into the ground, and leave the other quarter 3 ft. from the ground, on the theory that the chickens would not find this weak spot in your fence? In exempting anthracene, alizarin and indigo dyes and indigo from the surtax, that is precisely the theory on which the Kitchin bill proceeds, and it offers, at the suspended portion of the fence, an added bait for the chickens, by threatening to remove the surtax unless 60 per cent of the value of our total consumption is produced in this country within five years. That is about the same as if, in addition to building the fence as just described, you industriously sprinkled a lot of "chicken feed" so that it leads directly to this hole in your fence. That is the strategy of the Kitchin bill.

How shall the domestic value be computed? Shall the foreigner be allowed to add to his invoice value, duty, surtax, and any other usual charges? If so, he is given a considerable advantage over and beyond the 27 per cent start the Kitchin bill proposes to give him; this start may become 35 per cent and all the foreigners have to do would be less than 5 per cent additional work.

The Kitchin bill and the Hill bill each proceeds from the fundamental proposition that unless we protect the coal-tar dye and chemical industry in this country we are not going to have any such industry. That proposition may therefore be accepted as being true, conclusively established and the permanent consensus of public opinion; since it is indorsed by both the Democratic and Republican parties, free trade and protectionist alike. The only reasonable conclusion from this is that both political parties and the public each and all stand affirmatively committed to the national need of a coal-tar chemical industry in this country that shall be permanent, complete, self-sustaining, independent and fully capable of self-development; anything less than that would be a mere makeshift and a Dead Sea apple.

In the case of a given typical example of a cheap and

widely used coal-tar dye the Hill bill contemplates a net added protection ranging from 3.44c. to 2.95c. per lb.; the Kitchin bill contemplates a net added protection ranging from 2.08c. to 1.59c. per lb.; the American dye makers in 1908 wanted a net added protection of 3c. per lb. for that general class of dyes. The Hill bill gives the dye maker what he says he needs; the Kitchin bill does not. If we *really* want an American coal-tar dye industry and all it brings and may bring with it, why should we thus haggle? The reason seems to be that we fear that the Hill bill rates will create a set of "tariff robbers," and the assumption is that the Kitchin bill will not. Once we have a domestic dye industry we ought to be able to handle the "tariff robber" question on its merits, or are we so to confess that the only way we can check "tariff robbers" is not to have an industry?

Further, the Kitchin bill thinks that this protection might cost as much as \$2,700,000 per year; the Hill bill thinks this cost to be \$4,610,000 per year—either one a tidy sum, even for this nation and one which we should not light-heartedly incur.

Now, *why* should we have it? Surely not to add 6,000 people to our laboring population; this would be \$450 per year per person under the Kitchin bill and \$768 under the Hill bill. Surely not for 60,000 tons additional freight haulage, for this would be per ton of freight \$45 under the Kitchin bill and \$77 under the Hill bill; nor would it be good business to pay either sum so that certain stockholders could get \$1,660,000 per year in dividends. It cannot be a dollars-and-cents reason in this direction.

The Hill bill and the Kitchin bill were both introduced into Congress because of the insistence of dye-using interests that something be done to relieve the dye shortage and not at the request of dye-makers. These same interests for thirty years had kept down the duty on dyes, and were almost solely responsible for the disastrous tariff cut of 1883; the dye-using interests therefore have almost complete control of the dye-tariff policy of this country, and the dye and chemical making interests have no such control—not even a reasonable hearing. Under these circumstances it is reasonably clear that the dye-using interests can have any duty that may now be added removed at their pleasure. It is not sound, national policy to attempt to build up an industry in this country by protective legislation when the profits in that industry for some time will be dependent upon such protection and then have the power of altering that protective policy lodged exclusively in the hands of the customers of that industry to be exercised at their pleasure and in their interests only. When the situation is relieved why should they not have the duty removed? If they decided on that course the dye and chemical makers might be just as helpless to prevent it as they were in 1882 and continued to be down to 1913 and are, in fact, to-day.

It is true that the dye users also insist that arrangements shall be made so that such shortage cannot recur; but might they not brush that aside just as in 1882?

The *Journal of Commerce* of New York, on April 24, 1916, said:

"In the meantime dyes have been offered and sold here at fabulous prices in quantities palpably sufficient to keep all the largest textile plants moving. Somewhere and somehow supplies of dyes have been secured, for never before in the history of the United States textile industries have plants been run so full as they have been in the past six months, whether plants for printing, finishing and dyeing."

So that, from about the end of October, 1915, there has been no scarcity of dyes—provided you paid the price. Is that a "famine" or just a "corner"?

Had cotton not dropped violently in price in August, 1914, or, if you gentlemen had then been willing to pay 15c. for 6-cent cotton, there would not have been any such prompt demand for dyestuff-independence; we would probably not have heard much, if anything, about independence until fully a year later, if then. By so widely and publicly using the dye-stuff situation to offset the demoralized cotton market the cotton manufacturers simply invited others to come in and "corner" the dyes, which seems to have been efficiently done.

In now demanding that this country should never have been dependent upon others and that the dye-shortage, famine or corner, whatever you may choose to call it, should not have been permitted to exist, the dye-using interests are merely complaining against the logical, clearly foreseeable, but deliberately ignored results of their own deliberate and concerted acts.

To engage upon business merely to relieve a famine, real or artificial, is not attractive to anyone; to enter upon it to establish it upon a sound permanent basis is quite another thing. Frankly, all that the dye-using interests can safely be counted upon for is to want to relieve the situation, and they do not care how it is relieved—beyond that all is uncertainty, with the chances in favor of their successfully abandoning their desire for a strong domestic industry so soon as they can see reasonably clearly ahead for themselves, regardless of what the dye and chemical makers may think of the then existing conditions.

Legislation to foster this industry can be no more lasting than the reason for its existence. None of the reasons so far discussed can truthfully be said to promise sufficiently long life to achieve that result. They have all been successfully used in the past to prevent such protection; they are now urged to create such protection; there is no reason to believe that they will not revert to their former purpose at the very first opportunity, and that will no doubt come long before the industry is safely established.

These reasons touch relatively few of us. The question of having at all times equipment in this country and men capable to operate it to produce means of national defense, *i.e.*, high explosives, is one which promises to affect all of us. Now, what could a complete, self-contained and self-sustaining domestic dye industry making our total requirements of dyes so contribute? The most we could reasonably expect from it is that in a comparatively short time, say, a month or less, it could turn out 100 tons high explosive per day and could train enough chemists, superintendents, foremen and workmen fast enough properly to operate additional high-explosive-making plants as erected. In the past eighteen or twenty months we have learned, with every possible stimulus, to build from the ground up plants capable of making 80 tons of picric acid per day. How much TNT is made daily is not known to me with any certainty. From that point of view this contribution seems reasonably worth while. If we make 60 per cent of our requirements we very likely would make 60 tons in place of the 100 tons high explosive per day.

The massed coast artillery of our Atlantic and Pacific seaboard has to-day such a capacity of firing projectiles that if 5 per cent of the weight of those projectiles were high explosive, 100 tons high explosive, or one day's output, would last seven minutes. On the same basis, assumed the high-explosive producing capacity of the German coal-tar industry, as it existed just before the war, would last fifty minutes, or perhaps an hour.

Is it worth our while to have such a dormant capacity in this country? In a month we could then reasonably expect to be where otherwise we might not be much under a year? I think so.

If the final answer to that question be an equivocal "yes," and our army and navy officials are the only persons to answer that question in a way that would surely have the confidence of the public, then we have a reason for this special protective legislation that would be far more stable and far less subject to change than any other reason yet given. Such legislation would not be repealed nor altered for trade reasons alone; it would not be repealed until the coal-tar dye industry were really firmly established and we really did have this dormant capacity firmly under our own control. Surely we cannot be so impotent as a people, that we cannot devise ways and means successfully to resist "tariff robbers" and prevent their exploiting us under this kind of a cloak!

The same attitude should be taken if the answer be anything less than an unequivocal "no." In case of doubt play safe. It is better to be safe than sorry.

I have devoted so much time to a consideration of pending Federal legislation and to the precise location of the exact cause of all our dyestuff troubles because the future of the coal-tar dye industry in this country depends upon what and why legislation is enacted. It is no time for half-hearted measures. Either we have the substantial whole of the industry or we will have nothing of value in time of stress.

There is no reasonable question as to the wonderful expansion of coal tar and allied chemistry in the future. Fifty years ago no one would or could have dreamed of an industry of its present day magnitude—an industry that underlies so much of our textile, leather, printing, decorative and other industries; that is such a fundamental part of the great photographic industry; that provides remedies and medicines that reach to every hospital and almost every sickbed in the civilized world and adds to our comfort and well-being in such a multitude of directions as this industry does, and which also supplies so much and so many things to national defense. The best of these have not yet been discovered. There is much room for improvement. Just think of the advance in these lines during the past twenty years. Fifty, even twenty, years from now this combined industry may have grown so that its present permeation of the industrial life of nations will appear as a dwarf by comparison with its then influence.

Had we had a going dye industry in this country at the end of the 90's or early this century there is every reason to believe that we, too, would have been successful makers of the so-called vat dyes that make the wonderfully fast modern shades and would have had a substantial share in the making of all the other dyes and their intermediates and progenies.

The longer we delay getting this industry the more difficult the task will become. Shall we continue to sit by, let others do the work and reap the benefit and continue to be dependent upon others for all these things which are bound to become more numerous and more ramified than ever? There is no question that we can, if we will, make just as good qualities as anyone. We cannot do it unless we have the opportunity to acquire the experience. Shall we continue to be denied the opportunity, or does the nation want these things and actually want them earnestly enough to face the situation and pay the price without quibble and without haggle?

Great as has been our domestic progress in the past two years we cannot hope to keep it all without substantial economic help; to think that we will lose it all even without added help has no foundation in reason. Without help, and real help at that, we will continue to have, in normal times, an industry which is far from complete, and self-sustaining and self-developing and

bound to be a disappointment in time of stress and trial.

Now, which shall it be? The Hill bill, with reasonable certainty of success, or the Kitchin bill, with far less reasonable chance for success? The difference between the two may very well be the difference between substantial success and substantial failure. The differences in cost of finished fabric cannot be great—in most cases far from being large enough to pass along. In those few cases where the added cost turns out to be greater than can be borne they can be taken care of otherwise, and if necessary by needful tariff help. Certainly the difference in cost of finished fabric between the Hill bill and the Kitchin bill can hardly ever be large enough to pass along.

My own view is this: If the country is really honest and sincere in its loud and prolonged clamor for independence in this regard, now is the time to prove it by deeds. Plain, ordinary square-dealing and horse-sense clearly and imperatively demand the prompt enactment of the Hill bill rates, under which it will be none too easy sledding. The Hill bill rates are those that domestic dye-makers say are absolutely necessary to achieve this independence.

The dye users from 1882 to 1913 have deliberately and successfully played right into the hands of foreign dye-makers and against domestic dye-makers, and there is every reason to believe that they have not yet entirely overcome that habit. The Kitchin bill is the Hill bill pared down, cut down, and ham-strung, solely in the interest of dye users. Such quibbling, haggling and cheese-paring do not square with common sense, nor sincerity nor with fair-dealing toward the dye-makers who will have to carry the load. Even if, in years to come, the Hill bill should allow the existence of "tariff robbers" we can cross that bridge when we get to it.

The first thing to do is to get this industry; we can then take care of "tariff robbers," if and when there are any, if we want to.

If we choose the Kitchin bill and success should not attend it we will have lost just so much time and effort and will merely have shown again and for the sixth time that the dye-using interests cannot successfully prescribe tariff rates for the dye-makers. If we choose the Hill bill we will be giving the dye-makers their first real chance at tariff-shaping and also that which they say will enable them to create the complete and independent industry in all its substantial ramifications. If they then fail to create this industry it will be because the very best conclusion they could draw from the past failed to meet the then situation, and we will be better able to make the next step for success.

There is no less chance of encouraging rapacity on the part of the dye-makers under the Kitchin bill, should success attend it, than under the Hill bill should it be successful.

In summary, then, the coal-tar dye industry of the present has grown from obscure beginnings of little real world-wide promise to an industry that is of very wide ramifications in almost every phase of national and international commerce and industry. Experience in the past has shown that in order to get a foothold and develop in this country it must be aided substantially. We have had only an assembling industry. At present we have made great progress much of which will remain with us no matter if the present tariff be changed or not, but it will be in essence an assembling industry still. The future of the coal-tar chemical and allied industries is brighter and fuller of promise than ever. Its future in this country lies in our own hands, to make or to mar. Which will we do?

New York Meeting American Chemical Society

A meeting of the American Chemical Society will be held in New York City Sept. 25 to 30, inclusive, simultaneously with the Second National Exposition of Chemical Industries.

The first general meeting is to be held on Tuesday morning, and on Tuesday afternoon it is hoped to have a public meeting in the large hall of the City College with addresses by prominent men bearing upon "Chemistry and the National Welfare." On Tuesday evening a general "get-together" meeting or smoker will be held by the New York Section complimentary to the parent society, to which visiting chemists will be invited. On Thursday evening the American Electrochemical Society will give a smoker to which the members of the American Chemical Society will be invited, and on Friday evening a subscription banquet will be held.

Meetings divisions will be held on Wednesday, Thursday, Friday and Saturday mornings. One of the special features of the meeting will be general conferences on special subjects in which the chemists of the country are now interested. The idea of these conferences is to have some important topics such as Glassware and Porcelain; Steel Alloy Metals; Paper and Its Utilization; Oils and Motor Fuels; Convertibility of Plant; Medicinal Chemicals; Dyestuffs and Their Relation to Munition Factories; Industrial Alcohol, Acetone and Formic Acid. The discussion is to be started by some well-known specialists in these lines. No special program is planned for these conferences, but it is believed that chemists interested in these various lines will get together and many interesting points will be brought out which will be of mutual interest. The topics for these conferences have not yet been determined upon and suggestions are desired from members of the society. These suggestions will all be placed before the program committee and some six or eight topics selected therefrom. It is anticipated that two conferences will be in session each afternoon at the same time, one in the lecture hall of the Chemists' Club and one in the Grand Central Palace, where the Second National Exposition of Chemical Industries will take place.

The president's address will be one of the general papers at the public meeting on Tuesday.

The Divisions of Biological Chemistry, Physical Chemistry and Industrial Chemistry will hold a joint symposium on colloids on Wednesday and Thursday mornings. On Wednesday morning the symposium will be of a theoretical nature, in which the Industrial Division will not take part. On Thursday morning the symposium will be composed of industrial applications to colloid chemistry.

New York Meeting American Electrochemical Society

The thirtieth general meeting of the American Electrochemical Society which will be held in New York City Sept. 28 to 30 inclusive, in conjunction with the Second National Exposition of Chemical Industries, promises to be a most interesting and an exceedingly valuable meeting to attend. On Tuesday evening, Sept. 26, a general reception will be held at the Hotel Astor to which members of the American Electrochemical Society are invited. On Wednesday evening a general reception and registration will be held at the exposition. On Thursday morning will be held the "Made in America" technical session; on Thursday evening a complimentary smoker; on Friday morning a technical session; on Friday evening a joint banquet at the Waldorf-Astoria with the American Chemical Society. On Saturday an excursion may possibly be held.

The Thermal Decomposition of the Aliphatic Hydrocarbon Derivatives of Naphthalene

BY GUSTAV EGLOFF

The thermal decomposition of the pure aromatic hydrocarbons, benzene, toluene, xylene, cymene, naphthalene and anthracene has been studied.¹ The course of reaction due to temperature and pressure changes was found to be as follows: Higher homologs of benzene, lower homologs of benzene, benzene, diphenyl, naphthalene, anthracene, carbon and gas. In the following paper the aliphatic derivatives of naphthalene have been subjected to pressure and temperature conditions to form benzene and toluene.

SCOPE OF THE PRESENT INVESTIGATION

A tar oil resulting from the destructive distillation of coal contains compounds of the aliphatic and aromatic hydrocarbons. Tar acids and bases with naphthalene and anthracene are present in the tar oil. An earlier communication² showed that a tar oil did not decompose readily to form benzene and toluene. It has been found that naphthalene³ and anthracene under thermal and pressure conditions went mainly to gas and carbon, with no appreciable benzene or toluene formation. This did not preclude the possibility of benzene and toluene formation from the tar oil in quantity after extracting tar acids, bases, naphthalene and anthracene, leaving an oil chiefly composed of aliphatic derivatives of naphthalene.⁴ The removal of tar acids, bases, naphthalene and anthracene was necessary if benzene and toluene were to be formed appreciably.

DERIVATION OF THE OIL USED

The oil used was one derived from the thermal decomposition of coal, and is commonly known as a tar oil. This tar oil contained tar acids, bases, naphthalene, anthracene and aliphatic compounds of naphthalene. Table I covers the distillation analysis of the original tar oil.

TABLE I—DISTILLATION ANALYSIS OF ORIGINAL TAR OIL
Specific gravity, 1.007-15.5 deg. C.

Temperature, Deg. C.	Per Cent by Volume	Specific Gravity
125 to 150	4.0	0.860
150 to 200	5.5	0.945
200 to 250	47.0	0.975
250 to 300	26.5	1.005
300 to 350	9.5	1.037
Residue	7.0	
Loss	0.5	

The bases present in the tar oil were removed by treatment with sulphuric acid in the usual manner. The tar acids of the phenol, cresol type were extracted by

TABLE II—ANALYSIS AFTER REMOVAL OF BASES AND TAR ACIDS
Specific gravity, 1.005/15.5 deg. C.

Temperature, Deg. C.	Per Cent by Volume	Specific Gravity
125 to 150	8.4	0.930
150 to 200	42.0	0.999

250 to 300	5.0	
300 to 350	12.0	
Residue	0.6	
Loss		

the use of a sodium hydroxide solution. The oil, after bases, tar acid removal analysed as shown in Table II.

After removal of tar acids and bases the oil was

cooled with a salt-ice mixture so as to remove naphthalene and anthracene present. The oil after naphthalene and anthracene extraction gave the distillation analysis of Table III.

TABLE III—ANALYSIS OF OIL AFTER REMOVAL OF NAPHTHALENE AND ANTHRACENE
Specific gravity, 1.000/15.5 deg. C.

Temperature, Deg. C.	Per Cent by Volume	Specific Gravity
125 to 150	8.8	0.930
150 to 200	75.0	0.995
200 to 250	15.0	0.999
250 to 300	3.1	0.998
Loss	0.6	

This oil contained mainly alkyl and alkene derivatives of naphthalene.

EXPERIMENTAL PROCEDURE

The method of thermolizing the oil has been covered by Whitaker and Rittman.⁵ It consisted essentially of an electrically heated tube through which the oil was passed at a definite rate.⁶

The oil was cracked under conditions of pressure and temperature, which gave a liquid widely different in composition from the original. It was analysed for its benzene and toluene content by the specific gravity—distillation method⁷ and also by nitration. The nitro derivatives were determined as the mononitrobenzene and dinitrotoluene. The carbon formed was determined approximately by scraping it from the walls of the cracking tube and by filtering the suspended carbon in the thermolized oil.

The experiments were conducted at temperatures 600° C., 650° C. and 700° C., with pressures ranging from one to fourteen atmospheres.

EXPERIMENTAL DATA

TABLE IV—EFFECT OF TEMPERATURE AND PRESSURE ON THE PER CENT RECOVERED OIL AND THE PER CENT OF CARBON FORMATION

Temperature, Deg. C.	Pressure, Atmospheres	Per Cent of Recovered Oil by Volume	Per Cent of Carbon by Weight
600	11	68.5	8.3
650	1	75.0	1.5
650	11	50.0	5.0
650	14	45.0	10.0
700	11	33.6	29.0

TABLE V—EFFECT OF TEMPERATURE AND PRESSURE ON THE PER CENT BENZENE AND TOLUENE IN THE RECOVERED OIL

Temperature, Deg. C.	Pressure, Atmospheres	Per Cent Benzene	Per Cent Toluene
600	11	1.5	3.5
650	1	1.2	0.7

DISCUSSION OF EXPERIMENTAL DATA

A. The effect of temperature and pressure on the per cent of recovered oil and the per cent of carbon formation.

a. At constant pressure of eleven atmospheres a change of temperature from 650° to 700° C. decreased the per cent of recovered oil from 50 to 33.6 per cent, a difference of 16.4 per cent in the amount of decomposition. At a pressure of fourteen atmospheres and increasing the temperature 50° C. the decrease in the per cent of recovered oil was 23.6. This indicates that greater decomposition takes place at a higher pressure and lower temperature.

b. At constant temperature of 650° C. a change of pressure from one to fourteen atmospheres gave a greatly increased velocity of decomposition of the original oil. The yield of recovered oil decreased 30 per cent upon increasing the pressure from one to fourteen atmospheres.

c. The formation of carbon increases with increase of temperature and pressure. In this series of experiments temperature had a greater effect upon the carbon formation than pressure. At constant pressure of eleven atmospheres a temperature difference of 50° C. increased the carbon yield from 5 to 29 per cent. At constant temperature of 650° C. an increase of pressure from one to fourteen atmospheres, the per cent of carbon ranged between 1.5 and 10 per cent. Higher temperatures and pressures would have yielded the ultimate products—carbon and gas.

B. The effect of temperature and pressure on the per cent of benzene and toluene in the recovered oil.

The yield of benzene in the recovered oil increases with increase of temperature, at pressures eleven and fourteen atmospheres. At eleven atmospheres a change of temperature from 650° to 700° C. reduced the per cent of toluene from 4 to 3.9. At constant temperature of 650° C. increase of pressure increased the benzene content, whereas, the toluene reached a maximum and then decreased. Toluene formation is favored by lower pressure and benzene by higher.

C. The effect of temperature and pressure on the per cent of benzene and toluene formation on the basis of original oil used.

At fourteen atmospheres a change of 50° C. increased the yield of benzene from 1 to 3.2 per cent. Under similar conditions the toluene decreased from 2 to 1.8 per cent. A change from 650° to 700° C. and eleven atmospheres decreased the benzene and toluene yield. At constant temperature of 650° C. increase of pressure is favorable for benzene formation but not for toluene. A temperature of 650° C. and fourteen atmospheres is most favorable for benzene, whereas the same temperature and eleven atmospheres gives maximum toluene formation.

THE MECHANISM OF REACTION

Jones and Wheeler¹ in distilling coal at a temperature below the formation of hydrogen have found aromatic hydrocarbons present in the distillate. In accounting for the presence of aromatic hydrocarbons of the type of naphthalene they assumed the course of the reaction to be as follows:

Brooks² and coworkers account for the formation of

naphthalene by assuming that the naphthalene radical must be present. This assumption is deduced inferentially from decomposing a mixture of phenyl paraffins forming benzene, toluene and unsaturated hydrocarbons. They assume the course of the reaction to be as follows:

Jones³ found that under a temperature of 420° C. dihydronaphthalene gave a gas composed mainly of hydrogen and traces of higher olefins and ethylene. Decomposition of tetrahydronaphthalene at a temperature of 530° C. gave in the gas:

	Per Cent by Volume
Benzene and higher olefins	3.2
Ethylene	3.3
Hydrogen	80.5
Methane	9.2
Ethane	4.0

No analysis of liquid, if any resulted, was given.

In the thermal and pressure decomposition of aliphatic derivatives of naphthalene, benzene and toluene being formed the following mechanism of reaction may be assumed as having taken place. Though one must bear in mind that in complex reactions of hydrocarbon mixtures, no one reaction can be looked upon as taking place by itself, secondary and tertiary reactions must take place paralleling the primary.

When Jones³ heated di and tetrahydronaphthalene the products in the gas were benzene, ethylene, hydrogen, methane and ethane. Now the starting oil used in this investigation contained monomethyl and dimethyl naphthalenes⁴ with higher aliphatic compounds of naphthalene. If one heated monomethyl and dimethyl naphthalene the reaction products can reasonably be expected to take the following course:

Similar reactions would very likely follow using higher alkyl and alkene compounds of naphthalene.

Secondary reactions taking place at the temperature and pressure to which the oil was subjected would decompose the xylene, forming benzene and toluene. The decomposition of xylene giving benzene and toluene has been determined experimentally.⁵

Another direction of decomposing dimethylnaphthalene would be in the formation of allylene.

From the researches of Berthelot⁶ and other workers in the field of acetylene, it is certain that acetylene polymerizes, forming benzene and other aromatic hydrocarbons.

Jacobsen⁷ assumes the higher homolog of acetylene,

allylene to take part in the synthesis of toluene and xylenes.

From the above assumed mechanism of reaction, part of which is based upon experimental evidence, the formation of benzene and toluene may take place either by—

1. Direct decomposition of methylnaphthalenes.
 2. Formation of xylenes and subsequent decomposition.
 3. By synthesis from acetylene and allylene.
- In all likelihood the three reactions take place in successive steps, or simultaneously.

SUMMARY

1. An oil mainly composed of aliphatic derivatives of naphthalene derived from coal tar was subjected to the following temperature conditions, 600° C., 650° C. and 700° C. and pressures of one, eleven and fourteen atmospheres.

2. Temperature and pressure have a marked effect upon the decomposition of the original oil. Temperature favors decomposition to a greater extent than pressure.

3. The formation of carbon increased with increase of temperature and pressure. Twenty-nine per cent of the original oil went to carbon, at a temperature of 700° C. and fourteen atmospheres. The reaction of decomposition tended toward the ultimate products—gas and carbon.

4. The yield of benzene and toluene increased with temperature in the recovered oil within the limits of these experiments. Toluene formation increased to a maximum and then decreased as the temperature and pressure increased.

5. The maximum condition of 3.2 per cent of benzene formation on basis of original oil used was at 650° C. and fourteen atmospheres pressure. Two per cent of toluene was formed at 600° C. and fourteen atmospheres; and 650° C. and eleven atmospheres.

6. The mechanism of reaction has been assumed to take place, which is partially based upon experimental evidence, forming benzene and toluene—

1. Direct decomposition of methylnaphthalenes.
 2. Formation of xylenes and subsequent decomposition.
 3. By synthesis of acetylene and allylene.
- The three reactions take place either in successive steps or simultaneously.

National Fertilizer Convention

The twenty-third annual convention of the National Fertilizer Association was held at Hot Springs, Va., July 10 to 14. It was a most enthusiastic gathering, despite unfavorable conditions in the fertilizer industry during the past year, due to the cessation of imports. About 250 members were in attendance. The business sessions were held in the mornings, with the afternoons and evenings devoted to golf, riding and other entertainment features. A banquet was held Wednesday evening at which Hon. Theodore E. Burton and ex-Senator Chauncey M. Depew were the speakers. Great interest was shown in the educational work carried on by the Association during the last five years. Horace Bowker, secretary of the American Agricultural Chemical Company was elected president for the coming year; W. D. Huntington, vice-president of the Davison Chemical Company, elected vice-president; Irvin Wuichet re-elected treasurer, and W. G. Sadler re-elected secretary.

Blast Furnace Irregularities and Their Treatment—II

BY J. E. JOHNSON, JR.

Water Troubles

Water troubles are of two separate and distinct kinds, though one kind may, and generally does, lead to the other. These kinds are, first, an interruption either partial or complete in the cooling-water supply of the furnace; second, penetration of the water into the hearth of the furnace. This may be due, in a broad way, either to the failure of one or more cooling members, tuyeres, coolers, cooling plate and the like, or more rarely to the infiltration of water through cracks in the bosh packet or hearth jacket, or into the brick direct where it is not protected by metal jackets.

Failure of the water supply may occur in many ways: Failure of pumping plant, the bursting of the supply main, and as regards the individual cooling members, by the plugging up of the supply cocks with vegetable matter, fish or other foreign substance in the water.

The troubles are of two kinds—partial and complete. The effects of the two cases are very different. If the failure is complete, all the more important cooling members are almost certain to be burnt before the furnace can be cast and stopped. This is a calamity of the first order, and whether the failed members can be restored and the furnace put back into operation after the water supply is restored or must be blown out for repairs, depends upon the conditions of the individual case.

COMPLETE FAILURES OF THE MAIN WATER SUPPLY

These are among the most terrible of the accidents which can take place around the blast furnace, even if the fully supply be restored within a few minutes. The life of the furnace itself depends upon the existence of water cooling, always for the tuyeres, coolers, cinder notch and cinder cooler, and usually for many other cooling members, particularly the cooling plates in the bosh wall, when that type of construction is used. The failure of water on these for more than a second or two is generally sufficient to cause their destruction. The water remaining in them below the drainage level is very often sufficient to cause an explosion when they are burnt, and the small amount drained in from the water system is always enough to chill the furnace to some degree; if there is a small amount of water left flowing in the system, this is sufficient in a few minutes to put the furnace out of business for days.

When the water supply is restored after a brief interruption there are still great difficulties to be overcome. If it is known that any member has failed completely, the only thing to do is to shut the water off from it, but the solution of the problem is not generally as simple as this. It is almost out of the question to shut the water off from an active cooling member like a tuyere when the blast is still on the furnace, because under such conditions the member cut off is burnt out completely in a few minutes, and under the very best conditions the blast blows out through the opening with terribly destructive effect. In most cases this is accompanied by a heavy flow of cinder, and not infrequently by iron with its terrific cutting power, which is likely to lead to the destruction of other cooling members as well as cutting the exterior part of the furnace construction, the columns, hearth and bosh jackets, etc. If the first piece to go is a tuyere, such a sequence leads to the destruction of the cooler also in many instances. If, therefore, a number of cooling parts have failed under such conditions, it is absolutely essential to cast the furnace instantly; then the blast

can be taken off and the water can be shut off from the failed members without danger of serious consequences.

PARTIAL FAILURE OF MAIN SUPPLY

When only partial failure of the main water supply occurs, much can be done to reduce the seriousness of the resulting damage. The furnace must be cast and stopped without regard to any consideration except speed. The blast should be taken off the first instant it is safe to do so without filling the tuyeres with cinder. This does not reduce the temperature of the different zones of the furnace instantly, but it does reduce to zero the velocity of the gas currents, and this is of greater importance in diminishing the destructive power than reduction in temperature itself.

Generally the upper cooling members, particularly those above the mantle, if there are any, lose their water supply first as the head on the system falls. As described under "Construction," if these are made of iron the water circulation can generally be restored to them even after quite a long stoppage, but if they are bronze they generally melt and must either be replaced or else filled up with grout to form a physical support for the lining resting on them and to prevent the gas from burning out through them.

While the loss of these members is extremely serious, its effects are not so immediate or so disastrous as the loss of the cooling members in the hearth and bosh of the furnace. Here the tuyeres and coolers are subjected to the severest conditions by far, and if there be a partial supply of water remaining it should be diverted to them at the expense of all the other cooling members.

I have been through three partial failures of the main water supply, in each case from the failure of a fitting on the line, the breakage of which permitted the escape of the large part of the water supply and the diminution of the head on the system to the point where it was no longer sufficient to supply all the cooling members. In each case we escaped very serious damage by the same general course of procedure. The great difficulty in each case was to restore the broken fitting without shutting off the water supply completely, so causing the failure of all the members even when the furnace was stopped.

There should always be, and generally is, at every plant, a high-pressure water supply of relatively limited volume for fire service and the like, and this we had in each of the three cases mentioned, but in none of them was this supply nearly adequate for the cooling system of the furnace as a whole. In one case the supply was so limited that after the furnace was stopped the tuyeres were pulled out and the noses of the coolers packed with clay. This eliminated the tuyeres from consideration and permitted us to use the scanty supply available for the coolers and the lower rows of cooling plates. These we connected up by hose lines with the high-pressure supply and by driving the latter for all it was worth we were able to force enough water to these members to preserve them under shut-down conditions, though they would not have lasted 10 seconds with the blast on.

While this emergency supply was being connected, everything possible that could be done in advance toward replacing the failed fitting was made ready. Finally, when all was ready, the emergency supply was connected up, the regular supply shut off and the failed fitting removed, the new one was then inserted, the pipe coupled up and the regular supply turned on. In one case things were getting so hot with only the emergency supply that as soon as the new fitting was in place, and before any gasket was inserted in the

joint, we turned on the regular supply for a few minutes in that condition. It made a lively spray from the open joint, but sent enough cool water into the cooling members to give us a few minutes' grace, and in that time we slipped in the gasket and tightened up the bolts and then the regular supply was put on to stay.

It is on account of these experiences that I hold to the belief expressed in the chapter on furnace construction that two separate supply mains should be provided, each connected independently with the circular main around the furnace by a non-return valve set as closely to the circle main as possible. Then in the case of the failure of either main the other will continue to supply the furnace and no difficulty will arise from inability to shut off the break, because it is *between* the valve and the main, as happened in some of these cases.

OBSTRUCTIONS IN PIPES

One of the serious difficulties in a water supply liable to flood conditions is the accumulation of fine twigs, etc., which pass the main screen at the pump intake. These, combined with the silt and mud in the water, make it almost impossible to keep the circulation going on the most exposed cooling parts, especially the tuyeres. Because if the full water supply is diminished even a little, steam is generated and the pressure of this forces the water back into the supply pipe; the discharge then begins kicking and if quick action be not taken the loss of the tuyere is certain to follow within a minute or two, if not within a few seconds.

The best remedy for this difficulty is to have a strainer in the supply line, very much finer than the screen over the main inlet. This must be in duplicate and arranged for quick removal and cleaning; twin strainers are regularly built for this service and some of them are excellent in design and construction. The use of those when supplemented by extra care in times of flood water will cure the worst of the troubles from this source.

In order to guard further against this form of failure, the feed cocks from the circular water main are always made three-way and so arranged that by turning the plug into one position a wire can be run up through the bore of the cock into the supply main and the obstructing particle removed. In cases where this does not suffice to clear the pipe the three-way feature of the cock is useful because by turning it into position to connect the third or spare opening with the supply pipe and connecting a pressure hose onto what is ordinarily the discharge of the cooling member, the water current through that member can be reversed and most obstructions are removed by that treatment.

Certain waters carry in suspension vegetable matters such as the waste of paper mills, and these build up like fish scales in the pipes, in time obstructing them very seriously if not removed. They cannot be flushed out, because like fish scales they lie flat down-stream, but by a strong reversed current they can be ripped off in a few minutes and the pipe entirely cleared.

When the same cooling water is used over and over vegetable growths are apt to occur, much like the green slime seen on stagnant ponds, and these are very troublesome. They can generally be cured by the use of a very small amount of copper sulphate in the water.

EFFECT OF WATER UPON FURNACE OPERATION

In the article on thermal principles of the blast furnace, the subject of moisture in the blast has been treated at some length and the reason for the ruinous effect of water on the operation of the furnace has

been explained. It is well, however, to revert to the subject here and to emphasize its vital importance from the purely operating point of view, as distinguished from what might be considered by some the theoretical.

Let us assume a blast temperature of 1200 deg. and a critical temperature of 2750 deg. Fahr., then referring to our diagram of hearth heat available, it will be seen that the hearth heat per pound of fuel with no moisture is 1845 B.t.u. With $\frac{1}{2}$ lb. of moisture it is 1670 B.t.u., and with 1 lb. of moisture it is 1510 B.t.u. One pound of moisture per 1000 cu. ft. corresponds to 7 grains per cubic foot, and is an amount which is very common in the summer months in almost all climates and may readily be exceeded by 30 or 40 per cent in the South and during July and August in the North. A half-pound is a fair average amount for spring and fall conditions in the greater portion of the iron-producing district.

The difference between these amounts, $\frac{1}{2}$ lb. per 1000 cu. ft., represents the difference between fair average conditions and reasonably good conditions. Now, quantitatively, this corresponds to just about 10 per cent more hearth heat per pound of fuel with the former than with the latter, and this ordinarily corresponds to about 10 per cent greater fuel consumption with the higher quantity of moisture. This is as compared, not with good conditions of three-tenths of a pound, but fair average conditions, on the one hand, while as before stated, the higher quantity taken corresponds only to very fair summer conditions; as between bad summer conditions, say $1\frac{1}{4}$ lb. of moisture, and the good conditions just noted, the difference is between 1750 and 1430 B.t.u. of hearth heat per pound of fuel, a difference of more than 20 per cent, which corresponds very closely to what has been found in practice in many cases.

Taking our rough figure of 10 per cent increase in fuel for $\frac{1}{2}$ lb. per 1000 cu. ft. increase in the moisture in the blast, let us translate this into terms of actual water. On a large furnace blowing, say, 40,000 cu. ft. of air per minute actual, this would correspond to 20 lb. or a little less than $2\frac{1}{2}$ gal. of water per minute, a very small quantity to cause such a vast difference in fuel consumption. This makes it very clear that a heavy leak due to the failure of a cooling member which may discharge into the furnace in a solid stream 20 or 30 gal. a minute will very quickly drown the furnace out, while very small leaks are amply sufficient to upset the delicate equilibrium upon which all successful furnace work depends, for on the basis of the above figures $\frac{1}{2}$ gal. a minute corresponds to a reduction of 1 per cent in the hearth heat, and a change of that amount is usually sufficient to alter the grade of the iron appreciably.

There is one feature about water leaks which may make them even worse than moisture in the blast. The latter is disseminated with absolute uniformity throughout the whole combustion space of the furnace and therefore produces no local irregularity, but when a leak takes place it tends to chill one side of the furnace while the rest goes on undisturbed. This brings about an irregularity which, added to the ruinous effect of the water itself, in whatever form it may be, makes water leakage the worst dreaded enemy of successful furnace operation. I suppose that every furnaceman has had the experience of having a good working furnace begin to work poorly and finally, after endless trouble, finding a small leak in some cooling member, the amount of water passing through which seemed as though it must be absolutely insignificant, and yet when the defective member was replaced by a perfect one the furnace at once returned to its normal condi-

tion and showed every sign that the source of trouble had been removed.

THE LEAKAGE OF WATER INTO THE FURNACE

In striving to maintain the cooling members intact we have to meet conditions perhaps the most severe of any in the operation of the blast furnace. It is absolutely impossible to maintain the furnace without cooling. The water-cooled members must necessarily be very thin or they will burn up in spite of the water cooling, and yet it is absolutely essential that the water must not reach the fire, from whose effects it is protecting the structure. Nothing suffices to maintain these conditions and the satisfactory operation of the furnace which depends upon them, except intelligent construction in the first place, backed up by vigilant and experienced operation.

The inner ends of all the cooling members in the hearth and bosh are in immediate contact with the currents of molten material and gas while the tuyeres are thrust right out into both and are exposed to the constant wear of the coke and to the drip of the iron and cinder running down the bosh walls. These members, therefore, necessarily fail from time to time, either by wear or by being cut by a particularly active jet of iron striking them from above and perhaps in many other ways. These failures lead to the direct flow of water in the hearth.

To determine whether a member has failed or not is one of the most difficult tasks in the operation of the blast furnace, for a tuyere may have a hole $\frac{1}{4}$ in. in diameter burnt in it, through which enough water will flow to chill the furnace in an hour or two, and yet superficial observation does not show the diversion of this water from the regular discharge of the tuyere, so it does not do to shut off these cooling members indiscriminately, because every one so treated is instantly destroyed when the blast is on, and very soon even when the blast is off the furnace. Those so destroyed must be replaced at great expense in money and far greater in loss of time, to say nothing of labor, before the furnace is in shape to go again.

There is no general method of determining whether a certain member is leaking or not if the leak be a small one. The presence of hydrogen in the gas in large quantities can always be detected by watching the combustion at the stoves and boilers, but while this proves the existence of a leak it gives no evidence as to its location, and sometimes the furnaceman will be hunting for days on the suspicion, or perhaps the certainty, that water is going into the furnace, without knowing where it is coming from. In some cases the plan has been adopted of pulling every cooling member in the furnace, not always at one shutdown, but stopping for a half-hour or an hour after every cast and pulling as many as possible, testing these under pressure outside the furnace for leaks and restoring them to place when perfect. This involves an enormous amount of labor, but, as before explained, the destructive action of water on the furnace is so great that a tiny leak is enough to affect the action of the furnace very seriously, and in some cases so destructively that whatever measures are necessary must be used to find it.

Perhaps one of the best methods of determining leaks is to throttle the water supply of the cooling member until the stream from its discharge flows absolutely smoothly, without spatter due to initial velocity, and yet without any break in the stream. By holding a light behind a stream of this kind gas bubbles can generally be seen descending in it if the member is leaking. A necessary feature of this method of test

is to throttle the pressure of the water in the cooling member down below the blast pressure inside the furnace, so that the gas comes in through the leak instead of the water going out.

Another method particularly effective in case of a leaking tuyere is to run a rod in through the peep hole to the nose of the tuyere, leave it for a few minutes and pull it out. In case of anything but a very small leak, the rod is frequently wet on the end.

Very often leaks can be detected by the wetness of the aperture through which the cooling member is inserted. The water is forced back in some rather mysterious way and makes its way out to the outside of the furnace. This is generally an excellent indication, but sometimes the water is so inconsiderate as to travel from the defective cooling member around a half dozen perfect ones and out through the butt of one of the latter, so that it is not safe simply to turn off the water supply from a member which shows wet around the base without investigating further.

There is always a certain amount of gas around the bosh of a furnace, not coming from any particular region that can be discovered, but nevertheless present all around it; the smell of this gas is altered to some extent by the presence of water going into the furnace, and this sometimes serves for a preliminary indication. The master mechanic of a small plant once said: "If you see old Wash (the colored keeper) get up and begin to walk around the furnace with his nose stuck up in the air, you may as well get ready to change a tuyere after cast."

It is impossible to do justice in print to this subject, so vital to the successful operation of the furnace. Nothing but several years of hard knocks around the plant suffices to impart a satisfactory education on the subject.

In order to prevent the difficulties which arise from the entrance of water into the furnace, various efforts have been made to supply a water circulation in which the pressure should be lower than that in the furnace itself, so that any failure would result in a little gas blowing out through the discharge, but not in the entrance of any water into the furnace. One of the schemes which has probably occurred to many is to pull the water through the cooling members by suction rather than driving it through under pressure, but the practical difficulties of maintaining pipe joints tight against vacuum, and the greater complexity necessary in such a procedure, have prevented it from being put into practical use in this country, so far as known to me.

But while there is difficulty in actually sucking the water through the pipes, much may be done to reduce the pressure required to make it flow. The volume desired should be obtained by large pipes under the lowest possible head rather than by smaller pipes under higher pressure. Above all, the discharge pipe should be direct and as free from bends as possible, because the end of this pipe being open, its frictional resistance is the measure of the pressure which must be maintained on the cooling member to produce the required flow. I do not think that enough attention has in all cases been paid to this important detail.

Another matter worthy of attention is the regulation of the water supply of the different members according to their requirements. It is extremely simple to turn them all on full head and run all the water possible through them, but this not improbably takes more heat out of the furnace than is required; it certainly requires an excessive amount of cooling water, and, above all, it maintains an entirely unnecessary pressure upon the cooling member with consequent liability to heavy leakage in case of failure.

In regard to the tuyeres and very often the coolers, the full flow policy is generally desirable, because the conditions to which they are exposed in the furnace are so severe that it is a wonder that any amount of cooling preserves them and we cannot afford to take chances of diminishing their water supply, but for many of the other members, a very much smaller supply of water suffices and they should be throttled down to the point where the water begins to be appreciably warmed in its passage through them, unless this leads to a water supply so small that it is likely to fail accidentally. No member should ever be throttled to this latter degree, because complete stoppage of such a choked water supply is almost sure to take place accidentally sooner or later. In this, as in all matters of furnace operation, there is no substitute for experience and good judgment.

In addition to the penetration of water into the furnace through leaky cooling members, much trouble has arisen in time gone by from water soaking in through the brick work at unprotected points and particularly where the jackets are used, from water entering between the jacket and the brick and thence soaking into the combustion space. It would seem that this action could not occur in view of the pressure of several pounds per square inch existing in the combustion space, but that it does occur most furnacemen know to their sorrow. The explanation probably is that the capillary attraction of the brick is stronger than the blast pressure and so draws the water inward in spite of the pressure outward.

Leaks of this kind can best be prevented by correct design in the first instance. Where steel jackets are used, the greatest care should be taken to see that the upper sheet laps over the lower sheet in every case. The spray trough at the base of the steel bosh jacket, if one is used, should be made amply wide to catch drip and spatter. Where a steel tuyere jacket is used, troughs should be provided above each cooler-opening so that any stray water running down is caught in these troughs and guided down over the side of the coolers away from the furnace. The steel tuyere jacket should have a conical base, riveted water tight to it, to run out over the top of the hearth jacket so as to shed any water which may fall upon it outside the hearth jacket and prevent its running down between the jacket and the brick work. Above all, if any sort of external spray be used on the hearth jacket, the latter should be made as absolutely tight as a high-pressure boiler, otherwise the water will find its way into the brick work and working through this, reach the hearth.

After proper construction of this kind has been provided, continuous watch must be maintained to see that water does not break through the defensive armor of the furnace in some unforeseen way and so make its way into the combustion zone.

Productos de la Ingersoll-Rand is the title of a catalog issued in Spanish by the Ingersoll-Rand Company, 11 Broadway, New York. It is attractively and substantially bound and contains 124 pages replete with illustrations, descriptive matter and tabulated data. The catalog covers completely the company's line of air and gas compressors, vacuum pumps, reciprocating and centrifugal water pumps, rock drilling, metal and coal mining, prospecting and quarrying machinery and pneumatic tools for machine and boiler shop and foundry work. In short this catalog is a complete reference book which should be of great service to Spanish-speaking users of pneumatic machinery.

Flotation Experiments on a Joplin Tailing

BY W. A. WHITAKER, GEORGE BELCHIC, ROY NEAL AND
H. L. VAN VELZER

The Joplin district of Missouri-Kansas is one of the largest regions in this country producing zinc and lead in which flotation has not been generally recognized and adopted, although encouraging signs in this direction have developed within the last few months with the installation of the process by at least one company and with its investigation by two others. During the year 1915, this district produced zinc and lead ores to the value of nearly \$27,000,000.¹

One of the authorities on the district, in commenting on some results obtained in this laboratory has stated² that "if the mill recovery of zinc in the Joplin district, averaging nearly 150,000 tons of metallic zinc for the last four years, could be raised from an average of 60 to 65 per cent to an average of 70 to 75 per cent (the recovery by flotation at Butte is probably about 95 per cent) it would add 25,000 tons of metallic zinc to the output of the district. Moreover, the increased saving would make deposits workable which were too lean to mine profitably before and thus further increase the output of the district." This figure when based on 20-cent spelter would have meant \$10,000,000 added revenue in 1915, and when based on the present prices would add a proportionate amount to the present year's income. It is thus seen that flotation is an economic factor which must be reckoned with by those who are concerned with the future of this district.

However, in studying the possible application of flotation here, there are several economic as well as technical factors which should be carefully considered. It has been recently pointed out³ that most of the mills of the district will average from 100 to 500 tons capacity per day of 10 hours; that the waste material is of two kinds, namely, that resulting from sheet-ground ore and that resulting from soft-ground ore, and under the assumption that 35-mesh material is fine enough for flotation, that "a 100-ton mill treating soft-ground ore will supply enough material to keep a 15-ton flotation unit running" and "a mill treating 200-tons of sheet-ground ore in 10 hours would produce about 10 tons of floatable material, provided most of this material can be collected." These quantities need not be taken, however, as limiting considerations, since the possibility exists of crushing economically some of the coarser material and thus adding to the quantity of possible floatable mineral. Also, future possibilities in the district might include greater capital invested, involving in turn the formation of larger companies, the construction of large mills, and a consequent larger output of tailings. This would mean, of course, still greater justification for flotation.

The object of the investigation herein outlined was to help along the possible application of flotation in the district by determining the behavior of various oils, or mediums, when used on a particular tailing, thereby determining those that give the richest concentrations and the highest extractions. In this work it has not been overlooked that the tailings of the district will vary in character and in zinc content, that the constituents of the various mine waters will vary, and, also, that a combination of oils may produce richer froths than a single oil, and, if not, that such combinations may be more economical to use. Experiments now being carried on will attempt to determine these latter points. However, as a beginning, it was thought ad-

visable to learn the behavior of the single oils on a single tailing before trying on a larger scale the many possible combinations on several tailings, since such data might allow the anticipation of such combinations, besides pointing out other interesting facts. The experiments tabulated in this paper were conducted during the period from Nov. 1, 1915, to March 15, 1916. They constitute a continuation of the flotation investigations begun in this laboratory in 1914 and hitherto published in outline.⁴

Experimental

In studying the behavior of these oils, the tests were run under neutral, acid and alkaline conditions, and with variations in temperature, and in the amount of oil and acid used. Under these conditions the percentage concentration and percentage extraction were determined. The oils used group themselves as follows:

Vegetable products	Drying
	Semi-drying
	Non-drying
Animal products	
Wood distillation products	
Coal distillation products	
Petroleum products	

No attempt was made to include a variety of rare, or unusual oils, which would not be applicable because of their expense. Some of those included, however, will come under the latter objection, but they were used because they represented one of the above groups, and because of certain physical or chemical properties which it seemed desirable to have represented. These properties are grouped for convenience of study in Table I.

One of the most important considerations in successful flotation is the composition of the water in which the process is carried out. The presence of certain colloids, of unusual acidity or unusual hardness may render impossible a process which has been successful on a similar material when a different water supply was used. The introduction of soaps, or of soap-forming constituents, such as saponifiable oils and alkali, in order to produce good frothing, may be rendered useless if the mill water contains hardening constituents which will react with the soluble soaps, precipitating them as insoluble soaps and thus obviating the lowering of surface tension with its consequent frothing effect. It seems reasonable to suppose that some of the tests recorded in this paper as carried out in an alkaline pulp, especially those with saponifiable oils, were partly vitiated because of the high Ca and HCO₃ content of the water used. These same tests if carried out in distilled water probably would yield much better results.

It may not be inappropriate to suggest here that if laboratory flotation testing should ever become a standardized procedure the tests will be carried out in distilled water and the necessary corrections, allowances, or modifications needed will be based on the composition of the mill water where it is intended to install the process. Engineers located in city laboratories, far removed from the mining districts, who make a practice of testing various ores for their amenability to flotation are liable to fall into serious error by ignoring this point. Future developments in flotation may reveal the justification for softening, neutralizing or otherwise treating the waters that are used in flotation cells. It may be more economical to treat a water in this way than to add the excess of oil which otherwise may be required, or to sacrifice recovery, by reason of the unusual composition of the water.

The water used in these tests was ordinary tap water

TABLE I—PROPERTIES OF OILS

Kind of Oil	Specific Gravity at 20° C.	Viscosity at 25° C. (Engler Viscosity-Inometer)	Surface Tension (Capillary method)	Saponification Value	Chief Constituents of the Oil
Castor Oil	0.958	159.00	43.50	176 - 183	Ricindein and its isomers. Small amounts of stearin.
Corn Oil	0.925	10.40	30.60	186 - 193	Palmitic, stearic, arachidic, linolic, and oleic glycerides ^{glycerides} . Small amounts of acetic and formic acids.
Cottonseed Oil	0.924	9.70	29.50	191 - 198	Olein, lindein, palmitin, and stearin.
Linseed Oil	0.933	6.25	34.50	186 - 192	Palmitin, stearin, and myristin. Oleic, linolic and linolenic acids. Small amounts of unsaponifiable matter.
Oleic Acid	0.902	7.90	23.70	190	About 94% free fatty acid—oleic, and 3% unsaponifiable matter.
Olive Oil	0.913	11.50	35.20	189 - 196	Olein, lindein, and palmitin.
Rape Seed Oil	0.915	11.70	29.80	171 - 179	Stearin, rapin, erucin and 0.41 - 1.43 % arachidic acid.
Sunflower Oil	0.922	8.65	29.50	186 - 194	Linolic and oleic glycerides.
Tung Oil (China Wood)	0.938	39.00	39.00	190 - 196	Olein and 75% elaeomargarin; 10% oleic and 2-3% saturated acids.
Fish Oil	0.935	7.00	35.00	197 - 203	Glycerides of liquid and solid acids; valerianic acid and some sperm oil.
Eucalyptus Globulus	0.850	1.37	24.20	—	6% aldehydes (butyric, isovaleric, and capronic); 21% pinene; 41% cineol; 25% alcohols, small amount of camphene.
Oil of Hemlock	0.870	1.15	30.00	—	Pinene, cadinene, bornyl acetate, and camphene.
Wood Distillate	0.931	1.11	30.10	—	Methyl alcohol, acetic acid, acetones, hydrocarbons, and tarry products.
Crude Wood Turpentine Oil #75	0.889	1.12	30.50	—	Terpene, pinene, resin, formic and acetic acids. Small amounts of camphene, dipentene, and traces of aldehydes.
Refined Wood Cresosote Oil #200	0.974	1.50	28.00	—	Cresol, phenol, creosol, and guaiacol.
Crude Wood Oil #500	1.008	5.21	22.60	—	Light rosin oils, light tar oils, creosol, phenol, benzol, pinene, and dipentene.
Pure Pine Oil #5	0.935	2.23	23.30	—	Laevo-menthone, limonene, and some of the higher boiling terpenes.
Pine Tar Cresosote Oil #7	1.020	1.37	28.00	—	Methyl ethers of catechol and its homologues; phenol, cresol, dimethyl pyrogallate, pitch, and other hydrocarbons.
Special Pine Tar Cresosote Oil #8	1.036	8.23	24.20	—	Phenol, cresol, dimethyl pyrogallate, and methyl ethers of catechol and its homologues.
Wood Cresosote Oil #17	0.973	1.39	37.60	—	Cresol, phenol, creosol, and pitch.
"Tarco" (Coal Tar Oil)	1.056	7.41	31.20	—	Coal tar derivatives containing phenol, cresol, naphthalene, toluene, anthracene, pyridine, and quinoline.
"Creco" (Coal Tar Oil)	0.960	2.12	29.60	—	Phenol, toluol and homologues.
Coal Tar Cresosote with Carbonic Acid #22	0.976	1.21	28.00	—	Cresol, phenol, creosol, naphthalene, phenantrene, and pyridine.
Crude Carbonic Acid	1.027	1.93	30.60	—	Phenol, cresol and homologues.
Crude Petroleum (Kerosene)	0.844	1.81	32.30	—	Mixture of hydrocarbons of various series together with a small percentage of nitrogenous basic matter, oxygenated bodies, and organic compounds with sulphur.
Paraffin Oil	0.876	4.50	30.10	—	Mixture of hydrocarbons of the paraffin series, obtained by purifying and decolorizing the fraction boiling above 300°C. obtained in the distillation of crude oil.
Sludge from acid in water	0.918	3.50	29.70	—	Mixture of compounds that are removed with the sulphuric acid in the acid treatment of the various distillation products from crude petroleum, chiefly aromatic hydrocarbons, tarry products, and sulphonic compounds.
Sludge soluble in water	1.020	1.10	28.20	—	A special preparation of sludge.

* Mixed - 5 parts of water to 1 part of sludge.

It seems reasonable to suppose that the possible presence in any of the Joplin waters of acids, salts of calcium and of other metals, should not interfere with successful flotation, since many of the results tabulated here were successful in the presence of a relatively high acid and calcium content.

The tailing used in these tests is much finer than the average material for the district. It was taken from a pond in Galena and is described by the screen and chemical analyses given in Table 5.

The machine used was a small laboratory size of the mechanically agitated type. Lyster or Hoover design, and consisted of an agitating compartment and a floating compartment.

Method of testing: To the agitating compartment of the machine were added:

2000 grams of water

400 grams of tailing

varying amounts of oil (See Table I).

The mixture was agitated for 2 minutes with a

propeller speed of 1800 r.p.m. and for the following 5 minutes agitation was continued, with the door separating the two compartments, opened, so as to allow the froth to form and gather in the flotation compartment. The collected froth in the flotation compartment was removed by skimming and overflow, after a total of 7 minutes agitation, and was dried, weighed and assayed for zinc content. The machine was cleaned of gangue, and a fresh charge added.

Discussion

The following discussion is based upon the results tabulated in Table II. The term "neutral pulps" refers to pulps in which neither acid nor alkali has been used; by "low acid pulps" is meant pulps to which 4 lb. of concentrated sulphuric acid have been added per ton of dry tailing; by "high acid pulps" is meant pulps to which 8 lb. of concentrated sulphuric acid have been added per ton of dry tailing, and by "alkaline pulps" is meant pulps to which 8 lb. of sodium hydroxide have been added per ton of dry tailing.

Castor.—The highest concentrated was 47.5 per cent, produced by using 4 lb. of oil per ton of tailing in the low acid pulps. Increasing the amount of oil did not produce a richer froth in this acid condition, nor in the high acid pulps, nor in the neutral pulps. The same quantity of oil used in the alkaline pulp produced a very lean froth. Castor possesses the highest viscosity of any of the oils used. Extraction increased with increasing quantities of oil reaching a high point, 73.4 per cent, with 12 lb. in a neutral pulp.

Corn.—With this oil the richest froth, 47 per cent, was obtained under the same conditions as in the case of castor oil, 4 lb. of oil in the low acid pulp. Here, also, increasing the oil did not produce richer froths under any of the conditions tried. Extraction increased with increasing quantities of oil, reaching 55.43 per cent in a neutral pulp, and 77.50 per cent in an alkaline pulp.

Cottonseed.—The richest froths produced by this oil were obtained in a more acid pulp than in the preceding cases. Two (2) lb. of oil in the high acid pulp gave a 51.1 per cent froth. Increasing the oil did not increase concentration save in a very slight degree, where 8 lb. were used. Extraction increased with increasing oil reaching a maximum at 48 per cent.

Linseed.—In the case of linseed, also, the richest froths were produced in the high acid pulps reaching the highest concentration, 55.71 per cent with 6 lb. of oil. A lesser amount of oil, 4 lb., produced approximately as rich a froth. However, with this oil, extractions were higher in the low acid pulps. Linseed was used because it is a typical drying oil and because of its tendency to partially oxidize when subjected to extreme aeration, as would be the case in flotation, and become more viscous. Cotton-seed, rape seed and certain other oils behave similarly but to a lesser degree. It is interesting to note in this connection that the concentrate produced by linseed was the richest obtained in this series of more than 270 tests.

If it were possible to have a froth consisting only of water, air, oil and zinc sulphide, and with no gangue present, this froth when "broken" and dried should assay 67.1 per cent zinc, that is, the theoretical per cent of zinc is ZnS. The above concentrate which ran 55.71 per cent zinc is, therefore, an unusual case of mineral selectivity, and especially so, when we consider the zinc assay of the original tailing, namely 3.6 per cent. It represents a concentration of 1 to 15 pulps.

Oleic Acid.—Lean froths were obtained with this medium, the best being a 34.1 per cent concentrate with

OF TESTS

Temperature of Pulp 20°C.				Remarks.
Condi- tion of pulp	Amount of oil used per ton of ore pounds	Assay con- centrate percent	Percent extraction	
not tested	—	—	—	
4.0	0.2	19.80	23.30	In neutral and acid pulp the froth formed is a thin sheet and is not beneficial. Acid and high temperature forms a more permanent froth. Alkali added to the pulp forms a permanent froth.
20.0	1.0	28.30	77.50	In neutral and acid pulp at low temperature paste froths form, which are not beneficial, but these are of short duration. High temperature produces selective froths, which tend to form a frozen froth.
2.0	0.1	48.80	46.00	In neutral and acid pulp at low temperatures, brittle bubble froths form. High temperature produces selective action and alkali added forms pulp 4.
4.0	0.2	18.24	17.00	In neutral and acid pulp at low temperatures partial bubble froths form. High temperature tends to make a more permanent froth, which is not beneficial.
2.0	0.1	6.44	7.10	In neutral and acid pulp, viscous frozen froth forms. High temperature has no apparent effect upon the frothing properties of the oil. Alkali tends to increase the collecting power of the froth.
4.0	0.2	5.37	36.30	
8.0	0.4	16.60	41.00	In neutral pulp the froth takes the appearance of a scum or thin sheet. Acid is beneficial, while high temperature makes the froth brittle. Alkali tends to make a frozen froth.
20.0	1.0	16.28	46.40	In neutral and acid pulp at low temperature, brittle bubble froths form, which in large quantities of oil are used. High temperature increases the selective action of the froth.
4.0	0.2	26.30	38.20	In neutral and acid pulp a thin sheet or scum-like froth forms. High temperature tends to form a bubble froth, while alkali forms a viscous frozen froth.
20.0	1.0	21.50	33.00	When small quantities of oil are used there is scarcely any tendency to form a froth. High temperature is detrimental, but alkali tends to make a viscous froth.
4.0	0.2	31.00	28.00	In neutral and acid pulp at low temperature froths of the bubble type form, but in small amounts. High temperature destroys the froth, and alkali is beneficial in that it tends to form a fairly persistent froth.
2.0	0.1	22.10	71.00	In neutral and acid froths at low temperature thin and brittle froths form. High temperature creates a more permanent froth while alkali tends to form a viscous, frozen froth.
2.0	0.1	25.00	80.00	In neutral and acid pulp at low temperature good froths form. High temperature tends to rupture the froth, while alkali forms a viscous, frozen froth.
2.0	0.1	24.04	78.50	In neutral and acid pulp at low temperature good froths form. High temperature tends to rupture the froth. Alkali tends to form a viscous, frozen froth.
1.0	0.05	28.10	66.30	In neutral, acid, or alkaline pulp this oil will form viscous frozen froths showing poor selective action.
1.0	0.05	21.00	54.00	When used in large quantities this oil forms viscous froths which carry the gangue minerals as readily as the sulphides.
1.0	0.05	24.40	84.00	In acid, alkaline or neutral pulp the froth formed is viscous and frozen, showing poor selective action.
2.0	0.1	13.00	80.00	In neutral and acid pulp the froth forms almost instantly showing good selective action. High temperature tends to make for better selective action of the froth. Alkali increases the frothing action, but decreases the selective action.
2.0	0.1	12.00	60.00	In neutral acid and alkaline pulp, this oil produces viscous froths, which carry the gangue as readily as the sulphide minerals. High temperature has the tendency of further increasing the collective power of the froth.
1.0	0.05	21.21	84.00	In neutral, acid, and alkaline pulp at low temperature good froths form, poor in selective action. High temperature tends to rupture the froth.
2.0	0.1	23.18	68.00	In neutral, acid, and alkaline pulp, this oil produces viscous froths showing poor selective action. Temperature has but little effect upon the frothing properties of the oil.
1.0	0.05	47.00	50.00	In neutral and acid pulp at low temperature, large viscous froths form. High temperature and a large quantity of acid is detrimental. Alkali tends to produce a good selective froth.
1.0	0.05	37.40	42.00	This oil appears to behave in all respects like "Torco".
4.0	0.2	36.20	45.30	In neutral and acid pulp, this oil acts both as a frother and collector, forming frozen froths. High temperature is detrimental in that it tends to rupture the froth. Alkali is beneficial.
0.5	0.025	16.00	15.00	In neutral and acid pulp brittle bubble froths form. High temperature weakens the froth and alkali is in part detrimental.
4.0	0.2	36.40	45.50	With a large quantity of oil and pulp neutral there is a tendency for the production of good froths. Acid is detrimental in that it tends to form a viscous, frozen froth with good selective action.
NO	froth formed	—	—	The oil rises to the surface of the floating compartment without any tendency to form a bubble froth or even a scum froth.
not tested	—	—	—	This oil is a good frother and collector and forms a viscous frozen froth. Acid is beneficial.
not tested	—	—	—	This oil is a good collector but shows poor selective action. In the frothing properties this oil resembles "Torco", in the action of alkali, but with many of the oils.

3. American Coal Refining Co., Denver, Colorado.
 4. Sludge from
 een removed—Standard Oil Co., Indiana.

4 lb. of oleic in the low acid pulp. Extraction reached a maximum at 49 per cent in a neutral pulp.

Olive. — The best concentration here, 41.47 per cent, was obtained in the low acid pulp, using 12 lb. of the oil. The best extractions were obtained in the same pulps. Froths obtained in neutral pulps were lean.

Rape Seed. — A high acid pulp gave the richest froth with this oil, the same condition which produced the richest froths with linseed and cotton-seed oils. Four (4) lb. of oil in the warm high acid pulp gave a 45 per cent froth. Neutral pulps gave lean froths. Extractions were highest in the high acid pulps.

Sunflower. — Here, also, the high acid pulps gave the richest concentrates, 43 to 53 per cent, and the highest extractions. Other conditions produced noticeably poorer results. Extraction increased with increasing amounts of oil.

Tung. — This oil gave poor results and, in many cases, no froth was formed. A large quantity of oil, 20 lb., yielded a froth of 27.73 per cent and an extraction of 21 per cent in a low acid pulp. In the alkaline pulp, concentration was slightly less and extraction was slightly higher than in the low acid pulp.

Fish. — With this oil in the low acid pulp, a 36 per cent froth, the maximum, was obtained, but this was accompanied by a very low extraction, 5 per cent. In an alkaline pulp, concentration was slightly less, but the extraction was 28 per cent.

Eucalyptus. — Here the best concen-

trations took place in a neutral pulp with small amounts of oils. The richest froth obtained, 39.13 per cent, was produced by 2 lb. of oil. In the high acid pulps extractions were unusually high, reaching a maximum at 98 per cent with 4 lb. of oil.

Hemlock.—Good concentrations were effected in both neutral and low acid pulps by using only 1 lb. of oil. Increasing the oil did not improve these results though extractions increased as usual, reaching a maximum at 83 per cent.

Wood Distillate.—Concentration was highest here in the low acid pulp, reaching 37.4 per cent with 6 lb. of the medium. As before, extractions generally increased with increasing oil. However, an alkaline pulp with 2 lb. of oil gave a higher extraction, 78.50 per cent, than did the neutral and acid pulps which contained greater quantities of oil.

Crude Wood Turpentine, No. 75.—The highest concentration was a 39.60 per cent froth obtained with the use of 1 lb. of this material in a low acid pulp. The highest extraction, 80.60 per cent, was obtained in the same pulp when 2 lb. of material were used.

Refined Wood Creosote, No. 200.—The tests with this medium show relatively high extractions accompanied by low selectivity for the mineral. In a neutral pulp extraction ran to 96 per cent, but this was accompanied by a very lean froth, 9.6 per cent. The best froth, 32.12 per cent, was obtained in a low acid pulp with 1 lb. of the medium.

Crude Wood, No. 500.—The best results with this medium were obtained under the same conditions as in the preceding case, namely, the richest froth, 30 per cent, resulted from 1 lb. of the medium in a low acid pulp and the highest extraction, 74 per cent, from 2 lb. of the medium in a neutral pulp. In an alkaline pulp, 1 lb. caused an extraction of 54 per cent with a froth of 21 per cent.

Pine, No. 5.—Pine oil produced good froths in neutral and in high acid pulps, reaching the maximum concentration, 53.2 per cent, with 2 lb. of oil in the high acid pulp. Low acid pulps do not concentrate so well with this oil. Extraction was highest, 80 per cent, in the alkaline pulp.

Pine Tar Creosote, No. 7.—Lean froths, with moderately good extractions, characterized this medium. A neutral pulp with 1 lb. of the medium produced a richer froth, 26 per cent, than any of the other conditions tried.

Special Pine Tar Creosote, No. 8.—A low acid pulp produced the richest froth, 34.61 per cent, with 1 lb. of this medium. Extractions increased with increasing amounts of the creosote when in neutral and acid pulps, but in an alkaline pulp, with only 1 lb. of creosote, it was higher, 84 per cent, than under any other condition.

Wood Creosote, No. 17.—Low concentrations with some good extractions characterized this medium. The best concentrate, 23 per cent, and the best extraction, 88.2 per cent, were obtained in a high acid pulp with 2 lb. of oil.

Tarco.—This medium was one of two of those tried that gave a higher froth, 47 per cent, in an alkaline pulp than in either neutral or acid pulps. The next richest froth, 35.6 per cent, was produced with 1 lb. of Tarco in a low acid pulp. A high extraction, 88.5 per cent, resulted with 2 lb. of tarco in a neutral pulp.

Creco.—This material seemed to act in the same manner as tarco, but to a lesser degree. Here, again, the richest froth under the conditions tried, 37.4 per cent, was produced in an alkaline pulp. Also, the next richest froth, 33 per cent, was produced in the low acid pulp with 2 lb. of creco. Maximum extraction reached 80 per cent with 3 lb. in the low acid pulp.

Coal Tar Creosote with Carbolite, No. 22.—This medium produced the maximum concentration, 43 per cent, in a low acid pulp when 8 lb. was used. The same quantity of medium gave a 39 per cent froth in a neutral pulp. With an increasing quantity in a neutral pulp extraction reached 83.3 per cent. In an alkaline pulp, concentration was more effective per pound of medium used, 4 lb. yielding a froth of 36.2 per cent, which was a higher yield than that produced by an equal quantity under neutral or acid conditions.

Crude Carbolite Acid.—The maximum concentration, 41.03 per cent, was produced in the high acid pulp using only ½ lb. of the medium. Judging the comparative froths obtained in all tests by the weight of the oil or medium used, this froth obtained with the use of ½ lb. of crude carbolite per ton, was the most effective result of all those tabulated. Extraction reached a maximum at 47 per cent with 1 lb. in the low acid pulp.

Crude Petroleum.—Concentration was here highest in the alkaline pulp with a froth of 36.4 per cent 4 lb. Froths obtained in acid pulps were lean. In a neutral pulp 8 lb of this medium yielded a froth of 35.6 per cent. In low acid pulps, extractions were fair when large quantities of oil were used.

Paraffin Oil.—The peculiar behavior of this oil in its non-frothing property confirms a statement recently made that an oil must contain suitable colloidal matter in suspension in order to produce a froth. By reason of the treatment to which this oil has been subjected in order to render it colorless, odorless and tasteless, it is assumed that all colloidal matter has been removed from it.

Sludge (insoluble).—This material was tested under two conditions only, in neutral and low acid pulps. The froths obtained in the low acid pulps were slightly richer than those obtained in the neutral pulps. Extraction reached 66 per cent.

Sludge (soluble).—This soluble material was not so effective in concentration or extraction as the insoluble sludge, all results being uniformly low.

TABLE VI. HIGHEST CONCENTRATIONS IN NEUTRAL PULPS

The results of Tables 6 to 13 are taken from the several tests arranged under Table I, in order to show a few of the richest concentrates and the highest extractions obtained in neutral, acid, and alkaline pulps. Twenty-eight (28) oils or mediums were tested in each of the above pulps, and in all conditions, save the alkaline, most of these mediums were tested by using three (3) different quantities.

Conclusions

1. The tailing used is easily amenable to successful

flotation under many simple and economical conditions.

2. In general, the above tests on a zinc sulphide tailing show that in neutral and acid pulps, vegetable oils and the lighter wood distillates show good selection for the mineral and yield rich concentrates, while creosotic and phenolic mediums, on the other hand, do not show such selection between mineral and gangue, but yield high extractions. Some exceptions occur, however, and in the alkaline pulps the above observation does not apply.

3. The richest concentrates and the highest extractions were produced in the high acid pulp.

4. The most effective results probably would be obtained by using a good "concentrating" medium mixed with a good "extracting" medium, i.e. a combination of the mediums mentioned under (2).

Note.—Since the foregoing laboratory tests were made some successful experiments have been carried out at Galena, Kansas, with a commercial-size unit. Some of the oils listed above were used, and also combinations.

Electric Furnace Anniversary.—A banquet commemorating the first anniversary of the initial heat poured in the Gronwall-Dixon electric steel melting and refining furnace was given Saturday night, July 22, at the Detroit Athletic Club by the John A. Crowley Company of Detroit, who control the United States and Canadian selling rights of this furnace. Attending the banquet were the heads of the engineering, laboratory, metallurgical, operating, sales, and clerical departments. The pouring of the first heat in the Gronwall-Dixon electric furnace, located at Michigan and Hubbard Avenues, Detroit, was the beginning of the first electric steel industry in Detroit. During the past year more than 5000 tons of chrome-vanadium, nickel-chrome, nickel, and other high-grade steels, have been made and poured from this furnace. A new and modern plant is being completed in Detroit having 10-ton units with 30,000 tons yearly output.

THE NEW MASSACHUSETTS INSTITUTE OF TECHNOLOGY

A School of Chemical Engineering Practice

BY WILLIAM H. WALKER

In the address delivered by President Maclaurin at the dedication of the new buildings of the Massachusetts Institute of Technology, published in full in the July 1 issue of this journal, he stated, "This—the adequate supply of properly trained men—is the cardinal doctrine of industrial preparedness recognized by thinking men to-day as one of the greatest necessities of the times."

While there will always exist some difference of opinion as to what constitutes a properly prepared man, there are certain qualifications with which he must be provided. For example, he must be well grounded in science, trained in the applications of its principles to daily problems, have acquired engineering points of view and angles of approach, and have developed business perspective with relation to industrial work. In short, there must be produced the *potential* engineer. When a man has acquired a solid foundation in science, has become an accurate observer, an exact and logical thinker, and has developed a love for the application of this knowledge to the investigation and solution of the many problems which industrial practice presents, he has done marvelously well; but he still lacks much that goes to make the successful engineer.

While it is true that the resourcefulness in applying theory to practice, the training in the solution of industrial problems, the general business perspective, and self-reliance, which in time complete the man's education and make him a *creative* engineer is obtained in its entirety only by years of experience, there is much which engineering schools have accomplished to render more quickly available the scientific education of the embryonic engineer. Without well equipped mechanical and electrical laboratories it would be a long and difficult step to pass from the small apparatus and light load of a physics laboratory to the heavy responsibilities of a power plant. But in operating and testing the commercial-sized units with which mechanical engineering laboratories are readily equipped, a measure of self-confidence and an appreciation of responsibility are obtained not otherwise possible. In addition to all this, the student translates for himself the fundamental principles of physics as exemplified in the laboratory into the application of these same principles in units and processes of commercial size and value.

But such facilities have to a very limited extent been available for instruction in chemical engineering. The

important and oft-times controlling difficulties inherent in carrying on a chemical process on a manufacturing scale are not present when this same process is conducted in a chemical laboratory. To duplicate the apparatus which has been designed and built for factory operation is possible, and in many cases well worth while. But in order to study its performance the apparatus must be operated—a process for which it was designed must be carried out. This procedure is obviously expensive and at best limited in its scope. A student cannot acquire the self-reliance necessary to operate a high-pressure digester holding 25,000 gallons of acid by experimenting upon one of a few liters capacity. He cannot learn how to meet difficulties incident to handling a filter press, an electric furnace, a multiple effect evaporator, a rotary kiln, and so on, if he has access only to such apparatus as the laboratory can provide. That experience which means power to execute comes only from contact with commercial sized apparatus operating under the conditions imposed by practice.

Neither can the student obtain that training in the application of the principles of science to the problems of chemical industry on which successful industrial research so largely depends, without an opportunity to live with chemical processes which are being conducted on a large scale. It is true that the research chemist must be able to visualize the hitherto unaccomplished fact, but on the other hand, the undreamed accomplishments of the future, while using methods and equipment now unrealized, will also undoubtedly to a large extent employ the apparatus and the processes of to-day, although along new and varied lines. A familiarity with what does and does not succeed in present practice is the best foundation for that soundness of judgment so essential in every research worker, and most especially in those who are to direct and guide the activities of our industrial research laboratories.

In view of the impossibility of developing the type of engineer outlined without greater breadth of method and of contact than is possible in our educational institutions alone, it is generally recognized that the industries themselves have a duty to perform in this regard, and that without their co-operation educational accomplishment must remain imperfect. On the other hand, no satisfactory scheme involving industrial co-operation with educational institutions has hitherto been proposed, and the conception and inauguration of such a scheme cannot but represent an educational advance of the first order.

Within the last few years a comprehensive plan of great promise for the more adequate training of chemical engineers along these lines has been originated and developed by Mr. Arthur D. Little, a member of the Corporation of the Institute of Technology and chairman of the visiting committee for the department of chemistry. The plan has been enthusiastically adopted, and is based upon the idea of a close co-operation between the Institute and certain selected manufacturing organizations in representative industries. It involves radical changes in the Institute curriculum for chemical engineering, and the location of a part of the Institute's instructional activity in the manufacturer's plant.

As Mr. Little points out in his report to the Corporation of the Institute, "any chemical process on whatever scale conducted may be resolved into a co-ordinated series of what may be termed unit actions, as pulverizing, mixing, heating, roasting, absorbing, condensing, lixiviating, precipitating, crystallizing, filtering, dissolving, electrolyzing, and so on. The principles underlying each of these unit actions are the same, however different the materials operated upon may be. Thus in a gas absorbing system, the laws of counter current absorption which control the action of an ammonia scrubber do not differ from those involved in making sulfite digester acid. The number of these basic unit operations is not very large and relatively few of them are involved in any particular process. The complexity of chemical engineering results from the variety of conditions as to temperature, pressure, concentration, etc., under which the unit actions must be carried out in different processes, and from the limitations, as to materials and construction and design of apparatus, imposed by the physical and chemical character of the reacting substances. It is possible to so select a relatively few industries that there will be represented by them all of the important unit actions of chemical industry."

Experience has shown that when proper provision is made the performance of a piece of apparatus may be studied without materially interfering with its output. Thus the principles of multiple effect evaporation or of counter-current lixiviation can best be understood by making properly designed tests upon a working plant involving these unit actions. In other words, it is possible, under careful regulation, to use a manufacturing plant as a chemical engineering laboratory, and not cut down its production or influence adversely the quality of product. Some of the advantages of such a method of engineering practice over a laboratory equipped for instruction only are:

1. A first-hand knowledge of the machines with which the plant is equipped, operating under conditions imposed by practice, the processes involved being considered as unit actions, the factors which control their efficient performance, and a general knowledge of the cost of chemical apparatus in its relation to cost of installation and operation.

2. A study of the unit operations of the plant and the process which is being carried on, as examples of the application of the principles of science to industry, their interpretation in terms of physics, chemistry and mechanics.

3. A general knowledge of modern methods of factory management and control, obtaining thereby some familiarity with the problems presented by the human element in industry.

4. The education which comes from taking part in the work of the plant; in acquiring some degree of self-confidence in handling industrial processes and large-sized apparatus.

To carry into execution Mr. Little's idea, a *School of*

Chemical Engineering Practice has been organized, which will increase in scope as experience is acquired. For the present it consists of five stations selected to furnish opportunity in specific fields of broadest general importance in chemical engineering. Each station will include a small instructional laboratory, drafting room and conference room, and will be provided with a projection lantern, such special library, drawings, and models as may be needed. It will be in charge of a director, who will be a member of the Institute faculty.

Station A. Located with the Eastern Manufacturing Company, Bangor, Me. Here will be studied:

1. That most important application of the principles of electrochemistry to reactions taking place in solution, namely, the decomposition of common salt, with the formation of hydrogen, caustic soda and chlorine. The unit operations here available for study are electrolysis, multiple effect evaporation with separation of a crystalline precipitate, caustic soda purification and concentration; absorption of gas of low partial pressure; agitation of both heavy and light liquids, and sedimentation of sludge.

2. The manufacture of bleached spruce pulp by the sulfite process. This is a high pressure-temperature reaction under careful analytical control, which involves most interesting equilibria.

3. The manufacture of poplar pulp by the soda process. In this process a study of the losses of soda through the cycle of operations is a most instructive one. It involves precipitation, sedimentation, filter press separation, systematic lixiviation and washing, and a determination of the soda lost in furnace flue gases by the Cottrell electrostatic separation principle.

4. The boiling, bleaching, and beating of rags for paper stock, and the manufacture of bond and ledger paper. This is both beater and tub sized, and is partly drum and partly loft dried. The opportunities for chemical engineering study here are obvious.

Station B. Located at Everett, Mass., with the New England Gas & Coke Company. Without going into detail, the opportunities here offered are readily appreciated. The company operates large by-product coke ovens and water gas plants, with all the apparatus incident to the recovery of naphthalene, benzol, toluol, tar, ammonia, etc. Every opportunity is here presented to study those high temperature reactions of hydrogen with various hydrocarbons which have become so important in recent years.

Station C. Located at Niagara Falls with the Carborundum Company. High temperature electrochemistry is here represented in all its phases. Powerful electric furnaces of both the resistance and arc types are in operation, making a variety of products. The apparatus for pulverizing, with accurate separation, is here seen at its best, systems of sieving and screening, hydraulic classifying, and pneumatic separation being in constant operation.

Station D. Located at Stamford, Conn., with the American Synthetic Color Company. At this plant will be studied the chemical engineering of organic chemistry. Fractional distillation, sulfonation, alkali fusion, nitration, reduction, crystallization, with all the necessary apparatus, are but a few of the operations here available.

Station E. Located near Allentown, Pa., with the Atlas Portland Cement Company. Large scale operations involving crushing and grinding in many types of machines are here offered. The chemistry of combustion and furnace control is nowhere studied to better advantage than in the mammoth kilns of this plant.

To obtain the greatest good from such splendid opportunities it is clear that this school must be a part

of a consecutive and consistent course of study. Not only must an adequate scientific foundation be laid before undertaking this chemical engineering practice, but provision must be made for taking advantage of the directness of purpose and enthusiasm for further scientific study which the factory work will create. This is accomplished by providing a Master's course in chemical engineering of five years' duration, including the entire summer between the fourth and fifth years.

The first three years are identical with those of the four-year Bachelor's course in chemical engineering as now offered at the Institute. At the end of the third year the student will elect either to finish the regular course of four years, receiving therefor the Bachelor's degree, or to spend two years and the intervening summer in study and receive both the Bachelor's and Master's degrees. From those students who elect this Master's course, including the school of chemical engineering practice, the faculty will select those whose attainments and character as shown by their previous record of scholarship and by other information are such as to indicate that the course can be creditably pursued.

At the beginning of the fourth year the men so selected will be divided into five groups, and one group sent to each of the five stations for a period of six weeks. (Experience may prove that this is too short a time to accomplish the greatest good.) At the end of each six-week interval the groups will change stations, so that by Sept. 1 each group will have occupied each station. After from three to four weeks' vacation these men will all return to the Institute for the fifth year of advanced work, graduating the following June.

It must be kept in mind that the students going out into these various industries do not go as employees of the industry, but as students in the school of chemical engineering practice. It is intended that the work in the plant shall be wholly educational, and the men are to be under the control and direction, not of the plant organization but of the director of the station, a member of the educational staff of the Institute.

While it is intended to give the men as much industrial experience as possible, having them take shifts in the ordinary routine of the factory, such work will be directed throughout to secure the maximum educational result, and the interpretation of the experiences and results of work in the plant will be accomplished by conference and drawing room exercises, which will take up no small fraction of the time spent in each station. It is expected in this way to avoid the weakness and inefficiency of previous schemes of co-operation by making no attempt whatever to have the student an economic asset to the industry, but planning his whole activity for its educational return to the student himself.

To secure this high educational efficiency from the contact of the student with the industry, it will be noted that the student has completed substantially the equivalent of a four-years' course in chemical engineering before entering upon the school of practice. This will make possible the full appreciation of the significance of every fact and the interpretation of every experience in the light of fundamental principles.

The work of the fifth year is advanced in character, broad in scope, and almost wholly elective, the purpose being to take advantage of the student's enthusiasm and to allow him to specialize in the line in which he has found by experience that he has the greatest aptitude and interest.

But the plan is a co-operative one, and while it is confidently expected that in the work carried on by these students entirely for its educational value, there will result an accumulation of data, much of which will

be of service to the industry concerned, yet this prospective return is not figured as an asset to the plan. As a return for the use of the factory as a chemical engineering laboratory the Institute proposes to establish and direct for each company concerned a research organization devoted entirely to the solution of its individual problems. While a laboratory will be maintained at each station, the extensive research facilities of the Institute will be available for work of a special character, and the faculty of the Institute will function as a consulting staff.

The earning power of industrial research is now too firmly established to require any argument to demonstrate the possibilities for co-operative service which the plan possesses. It is earnestly hoped that in it may be found an effective method by which science may be more closely linked to industry for the lasting benefit of each.

Hygroscopic Properties of Sodium, Potassium and Ammonium Nitrates, Potassium Chlorate and Mercury Fulminate

BY GUY B. TAYLOR AND W. C. COPE

One of the most important properties of substances used in explosive manufacture is that of behavior toward moisture. Thorough drying of many of the ingredients of explosives is required before mixing and many explosives must be packed in moisture-proof containers to prevent subsequent moisture absorption from the air.

The following experiments were undertaken by the Bureau of Mines in connection with studies of detonators (blasting caps) as the failure of a detonator is often a serious matter, and many failures are attributed to wet composition in the detonator charge. Precise information was sought regarding the conditions under which the mercury fulminate-potassium chlorate mixtures generally used in detonators would take up moisture from the air, and the rate at which it was absorbed. The salts sodium, potassium, and ammonium nitrates, are much used in explosives and were included in the studies, the methods of which are given below.

The behavior of soluble salts, not forming crystalline hydrates, toward atmospheric moisture follows very simple laws. If the partial pressure of the water vapor in the air exceeds the vapor pressure of the saturated solution of the salt, then the salt will take up moisture; if the partial pressure of water vapor in the air is less than the vapor pressure of the saturated solution no moisture will be taken up by the salt, but it will lose water to the air. If the two pressures are equal, then equilibrium occurs, and there is no exchange of moisture between the salt and the atmosphere. It should be noted, however, that this state of equilibrium does not correspond with any definite water content of the pure salt. Since the vapor pressure of pure water is always greater than that of any aqueous solution, it is evident that any substance containing a soluble constituent can never be in equilibrium with an atmosphere saturated with water vapor.

Observations concerning the absorption of atmospheric moisture have been made by various investigators: fertilizer materials by Brownlee,¹ soils by Lipman and Sharp,² and black powder by Kullgren.³ Studies on rate of absorption of moisture by sodium and ammonium nitrates, and explosives containing these salts

⁴Z. ges. Schtess-Sprengstoffw.—6, 364 and 385.

when stored over sulphuric acid solutions have been made by the French Explosives Commission¹, Busnikoff² and Schuyten³ have also studied the rate of moisture absorption by salts.

Rate of Moisture Absorption in a Saturated Atmosphere

In measuring the rate of moisture absorption, the material was exposed in an open porcelain crucible over water under carefully regulated conditions and the increase in weight noted after lapse of certain periods of time. Ordinary quart jars closing with glass tops and spring clamps were filled 2 cm. deep with distilled water; into each jar was placed a copper wire tripod for supporting one crucible. The jars were then closed and submerged completely under water in a large thermostat. When sufficient time had elapsed for jars and contents to come to the bath temperature, they were elevated so that the necks emerged, the tops removed, and the crucibles placed on the tripods. After closing, the jars were again submerged. In order to prevent possible condensation of moisture the crucibles were warmed slightly above the bath temperature before being placed in the jars.

The thermostat was a large tank of water, 30 by 26 by 20 in., electrically heated and stirred and controlled by a toluene thermo-regulator within less than 1/10 deg. Keeping the jars at a constant temperature prevented condensation of moisture on the walls and assured constant conditions of humidity.

When a crucible was removed from its jar, it was covered with an aluminum cover and weighed immediately since it lost weight fairly rapidly in laboratory air. Each result was obtained from a separate crucible, none being returned to the jars after weighing. The crucibles were about 2 cm. deep and had flat bottoms 3.7 cm. in diameter so that the material was spread out over a surface of about 10.75 sq. cm. The following results were obtained at 25 deg. from 2.0000 grams of

material. The salts used were highest grade C. P. preparations, the ammonium nitrate Bakers and the other three salts Kahlbaum's "brown label." The fulminate-chlorate mixtures were taken from commercial detonators (blasting caps).

If the increases in weight be plotted against time the points for the pure salts fall very closely on straight lines. The curve for a mixture of the two salts, sodium and potassium nitrates, with only 5 per cent NaNO_3 first follows the NaNO_3 line and then inclines toward the KNO_3 line. (See Fig. 1.) The points for the two potassium chlorate-mercury fulminate mixtures lie close to the KClO_3 line. These results are as may be ex-

FIG. 1—HYGROSCOPIC CURVES

pected from theory. The vapor pressure of a saturated solution in equilibrium with two solid salts will be at least as low as that of the constituent whose saturated solution vapor pressure is lower, which will in general be the more soluble salt. The NaNO_3 — KNO_3 , containing only 5 per cent of the former begins to absorb moisture at the rate of pure sodium nitrate, which becomes slower as the amount of water taken up increases and the NaNO_3 goes into solution, eliminating one of the solid phases. Mercury fulminate is so slightly soluble that its influence in lowering the vapor pressure of the saturated solution of potassium chlorate is small, and mixtures of these two salts take up moisture at about the same rate as the pure chlorate.

It will be noted that the chlorate-fulminate mixtures absorbed approximately the same actual weight of moisture in a given time as the pure chlorate although the quantity of actual chlorate present was only one-tenth and two-tenths as much. It was found by experiment that in thin layers and with the same exposed surface, the quantity of moisture absorbed in a given time was

independent of the weight as well as the fineness, within certain limits. For example 0.5 grams KClO_3 absorbed the same weight of moisture as 2.0 grams when exposed to a saturated atmosphere under identical conditions.

The results of Table II were obtained by exposing 2.0 grams of the salt over water in the same manner as above but at 35 deg. C.

TABLE II

	Hours	H ₂ O Absorbed, Grams
KNO_3	1 1/4	.0310
	4	.0612
	4 1/2	.0733
	10 1/2	.3137
KClO_3	20 1/4	.0847
	44 1/4	.1740
	68	.2887

Sodium nitrate in a partially saturated atmosphere, that is, over a saturated solution of potassium nitrate absorbed moisture as follows, 2.0 grams at 25 deg. C.:

7 hours	.1218 g.
16 hours	.2628
39 1/4 hours	.6955

Several experiments were made by exposing KNO_3 contained in vessels of varying heights and diameters filled to different depths with the salt. The weight of moisture absorbed in a given time in a saturated atmosphere is very materially affected by all these factors. In tall weighing bottles the rate of diffusion of water vapor evidently played an important part in determining the result. These results emphasized the importance of constant conditions in obtaining comparative results with the several materials. It should be pointed out, however, that the most important condition is maintaining constant conditions of humidity. For this reason exposing substances on watch glasses over water in ordinary desiccators at room conditions is a wholly unsatisfactory procedure for comparing the relative hygroscopicity or deliquescence.

Vapor Pressure of the Saturated Solutions

Marshall¹ has arranged a table of "relative deliquescence" of crystalline substances used in explosives assigning the value 1 to KNO_3 . The relative humidity, i.e., per cent air saturating in equilibrium with each salt for which there was no direct data, was calculated from Raoult's law. This figure subtracted from 100 and divided into the value for KNO_3 gave the "relative deliquescence." The values thus obtained at 20 deg. were for NH_4NO_3 , 7.6, NaNO_3 , 3.4, KNO_3 , 1.0, and KClO_3 , 0.23, while from the writers' experiments at 25 deg. C. the values are 6.3, 4.0, 1.0, and 0.23 respectively, which accord very well with Marshall.

Marshall's calculations are based on the assumption that the rate of moisture absorption is proportional to the difference between the partial pressure of water vapor in the air and the vapor pressure of the saturated solution. If this is true, from a knowledge of the vapor pressure of the saturated solution of one salt and the relative rates of moisture absorption in a saturated atmosphere, it ought to be possible to calculate the vapor pressure of saturated solutions of other salts.

The best available vapor pressure measurements of saturated solutions at ordinary temperatures are those of Speranskii.²

He used a tensimeter and measured the solution against distilled water. In the following table in the columns headed "calculated," the results were obtained from Speranskii's value for KNO_3 , 21.94 mm. at 25 deg. C. and our results on moisture absorption, together with Regnault's values for the vapor pressure of water, 23.55 mm. at 25 deg. and 41.83 mm. at 35 deg. C. These values for water are lower than those now generally accepted but were used in order to make use of Speranskii's formulas in calculating the observed vapor pressures of the saturated solutions.

	25 DEGREES		35 DEGREES	
	Calculated	Observed	Calculated	Observed
NH_4NO_3 . . .	13.4 mm.			
NaNO_3 . . .	17.11			
	17.25 (a)	17.32		
KNO_3 . . .	21.94	21.94	37.95	37.59
KClO_3 . . .	23.18	23.02	41.13	40.77

(a) Calculated from results over KNO_3 solution
(b) Used in all calculations.

The agreement between the observed and calculated values is well within all the experimental errors.

Absorption of Moisture by Detonators

The results obtained with the detonator compositions of mercury fulminate and potassium chlorate showed that the hygroscopic character of these compositions is almost entirely due to their chlorate ingredient. Tests were then made with commercial detonators of different grades, storing them over water in the jars in the thermostat. The results obtained showed that the rate of absorption is the same for all detonators having the same diameter, and is independent of the chlorate content and weight of the charge. The actual rate of absorption is shown to be very nearly proportional to the differences in the vapor pressures of pure water at the two temperatures and the vapor pressure of KClO_3 saturated solution. No. 5 detonators do not properly detonate with a moisture content as low as 0.01 gram per detonator. It should be noted, however, that fulminate-chlorate composition does not absorb atmospheric moisture at all unless the air is almost saturated, that is about 97 per cent between 0 deg. C. and 35 deg. C. a condition that obtains in practice only under exceptionally bad storage conditions.

MOISTURE ABSORPTION BY DETONATORS

Time, Days	MOISTURE ABSORBED AT 25 DEG. C.			Time, Days	MOISTURE ABSORBED AT 35 DEG. C.		
	L-178	M-54	M-1661		L-178	M-54	M-1661
2	.0020	.0019	.0016	3	.0080	.0080	.0082
4	.0041	.0038	.0038	8 1/2	.0217	.0215	.0222
6	.0061	.0061	.0065				
17		.0178	.0186				
25	.0202						

L-178—No. 5 detonator containing .50 gram charge of 90 per cent fulminate and 10 per cent chlorate.

M-54—No. 2 detonator containing 1.45 gram charge of 90 per cent fulminate and 10 per cent chlorate.

M-1661—No. 8 detonator containing 2.00 gram charge of 80 per cent fulminate and 20 per cent chlorate.

SUMMARY

The results described in this paper show that the hygroscopic properties of salts are a function of the humidity of the air and the vapor pressures of their saturated solutions. The relative rates of moisture absorption are proportional to the difference between the

¹Marshall, A.: "Explosives: Their Manufacture, Properties, T. 1 and History," McGraw-Hill, 1914, p. 314.
²Z. physik. Chem. 79, [1], 1913, p. 6.

partial pressure of moisture in the atmosphere and the vapor pressure of the saturated solution of the salt.

From a measure of moisture absorption, vapor pressures of saturated solutions may be calculated.

The tendency of detonators (blasting caps) to take up moisture from the air has been shown to be almost entirely due to the potassium chlorate which they contain.

Revision of Our Chemical Statistics

BY BERNHARD C. HESSE

In a paper presented at the Philadelphia meeting of the American Institute of Chemical Engineers it has been pointed out that our chemical statistics need revision; a general plan or outline of plan therefore was then presented. At the Seattle meeting of the American Chemical Society in September, 1915, a committee was appointed to devise some practical and practicable way of obtaining such revision and of putting it into useful and serviceable effect. The organization of that committee was not completed until June, 1916. The reason for this delay is that service upon this committee entails a large amount of very difficult and most tedious labor, and men hesitate to assume such added responsibilities. Successful execution of this plan calls for co-operative thinking and planning on the part of all members of all chemical societies of this country and of all those engaged in chemical pursuits of any industrial or commercial aspect in this country.

Inspection of the lists of European countries for the past twenty years, so far as they relate to chemicals and allied materials, shows that these lists have been very greatly expanded and indeed much more so than our own.

In general, each European country seems to arrange its list with a view of telling its own people the most about other peoples and of telling other peoples as little about their respective affairs as is convenient, particularly in those items which are capable of high diversification. For example, the German list divides 120,000 short tons, or \$54,250,000 = 21.5 cents per pound of coal-tar dyes into four items only; photographic chemicals totaling 3080 short tons, or \$2,000,000 = 32.5 cents per pound, are lumped into one item, and 1320 short tons, or \$5,300,000 = \$2 per pound, synthetic pharmaceuticals also take up but one item. These six items total 124,400 short tons, or \$61,550,000, and average \$495 per ton, or 24.7 cents per pound, and cover fully 1800 different articles of manufacture, only few of them closely related; 123 short tons of various alkaloids and their salts of a total value of \$1,750,000, or \$14,220 per ton, or \$7.11 per pound make up one export item.

On the other hand, Switzerland in its lists is more diversified as to its imports from Germany than Germany is in its list of exports to Switzerland; in fact, Switzerland seems to enter and report trademarked or proprietary synthetics and the like as such; our own lists do this in isolated cases only.

German statistics for the calendar year are published within the first five weeks of the succeeding year; our own reports are two or three months later.

On its face, it seems plausible that if we are now to diversify our domestic chemical industry rapidly, and with the fewest false steps and commercial or industrial calamities, we should be advised in some authoritative manner as to the nature of our domestic market

as it is now and may develop to be in the future. If under these conditions we do not properly develop our markets and our domestic manufacture, we at least cannot reasonably raise the defense that we did not do better because we had no way of determining what our country's needs were, and therefore could not intelligently plan our independence from foreign supply sources.

I am encouraged in a belief in this utility and benefit by the rather large number of inquiries that have been made of me personally, orally and by letter, within the past twenty months for information as to the domestic consumption of this, that or the other imported article, and in only the fewest instances have I been able to dig up an answer that filled the bill.

It seems to me that there can be no debate on the general proposition that the more we know about our market requirements the more likely are we to build up a domestic industry. Add to this the fact that at comparatively little added expense our federal government, through one or more of its departments, can gather and promptly publish such added information, and it seems to me to be conclusive that the chemists of this country should get together, make up a list of such specific added items they need to be informed about, and indicate such further diversifications of items as to them promise the greatest help in the future.

We can rest assured that the number of different chemical materials and products that this country will use and continue to use will be not at all diminished in the future, but quite on the contrary will be greatly and very likely rapidly increased. The longer we put off such diversification of our lists the harder the task of future diversification will become; it will certainly not become any easier.

Such a request for added information has nothing in common with asking for a subsidy or a bonus or added tariff protection; it is simply a request to be better informed as to the requirements of the public so that we may more intelligently work towards our nation's industrial independence of foreign supply sources; in so helping us the public will be helping itself.

In presenting to the proper authorities a request for added information we must make as reasonably sure as possible that whatever is presented is not half baked, but is as mature as circumstances and conditions will permit; that it meets with and embodies the views of the great majority of those likely to be affected by this information, and that there is a reasonable stability to that list; such request should be in as definite final form as possible.

Clearly, the constructing of such a request is by no means whatever the duty of any one man or of any small group of men; it is a duty in which every person in the country engaged in the making, selling and distributing of articles of this class fully shares; in fact, it is everybody's business. The committee of the American Chemical Society can act merely as a clearing house for requests, and then put them into a form that will be likely to receive the sympathetic attention and enlist the active co-operation of the officials who must supervise the details of gathering and publishing such material.

As chairman of this special committee of the American Chemical Society I have prepared a consolidated list of articles used or produced in or by chemical industries as they appear in the most diversified commercial reports of Austria, France, Germany, Great Britain, Italy, Sweden and Switzerland; italicized entries are to be found in the most diversified U. S. lists. This consolidated list is as follows:

LIST I

I.—MALT, OIL, FRUITS, INDUSTRIES, PLANTS, FRUITS AND PLANT JUICES.
Malt, excl., burnt and ground.
Rapeseed.
Castor beans.
Legs and sunflower.
Lansed and meal.
Palm kernels.
Kopra.
Hops.
Madderroot, Quercitron and other dye plants.
Opium.
Kino.
Acic and other fruit and plant juices.

II.—FERTILIZABLE PRODUCTS FOR INDUSTRIAL OR MEDICINAL USES

Cinchonabark.
Rhubarb root.
Cucum.
Cudbear.
Caraway, Iceland moss and other crude lichens; Tamarisks, stick-cinnamon; berries, leaves, flowers, etc. for medicinal uses. Insect powder and flowers.
Taro for coffee.
Vegetable waxes in natural state.
Wood for wood pulp, etc.
Wood charcoal and powder, charcoal briquettes.
Wood, flour and excelsior.
Roots for distillation. Roots for medicinal use.

III.—DYEWOODS AND TANNING MATERIALS

Logwood.
Fustic, Brazil wood.
Oreic.
Ground or fermented dyewoods.
Quabracho and other woods, in blocks.
Quabracho and other woods, ground.
Algarobilla, Dividivi and other n. s. p. f.
Palon.
Nygalls.
Myrabolans.
Cassia (brown and yellow).
Gambier (crude or refined).
Oak bark.
Coniferous barks.
Mimosa, mangrove, maletto and other tan-banks.
Oak, pine and chestnut—extracts.
Myrrail—extract.
Quabracho—extract.
Smacch—extract.
All other tanning extracts.

IV.—RESINS, LAKES, VARNISHES AND PUTTIES

Turpentine resins.
Kauri and other copals.
Banour, akaroid and other resins, oilbanur and other soft resins, gum-resins.
Gum-lac.
Shell-lac.
Acacia, ocakon, cherry, cutera and bassora-gums.
Tragacanth.
Scammony.
Gum varnishes, Bird-lime ex linseed oil.
Spirit varnishes. Shellac-putty.
Lacquers (non-spirit), asphalt varnishes, coach varnishes.
Sealing waxes.
Putty and putties n. s. p. f.
Asbestos pastes, asbestos pigments, asbestos putty.
V. CEMENTS AND CEMENTS
Cautchouc, crude or refined
Gutta percha, crude or refined.
Balata, crude or refined
Rubber, scrap or waste.
Cautchouc substitutes.
Couphon and manna.

VI.—ANIMAL AND VEGETABLE FATS AND OILS

Hog lard.
Oleum-caryne.
Cream-fat, beef marrow, etc.
Cream-fat tallow.
Beef and mutton tallow.
Bone-fat, fat-waste, stearin-oils.
Fish, whale and seal oil.
Fats, etc. from fish, whale and seal.
Horse fat, deer tallow, etc.
Pape oil.
Linseed oil.
Neau-oil.
Peanut-oil.

SEEDS AND

Olive oil.
Lavet and sulfur oil.
Cotton seed oil.
Castor oil.
Riceh, bone, corn, poppy, sunflower and other fatty oils.
Fat-oils in tins, bottles, etc.
Cocoa butter.
Cotton seed stearin.
Palm oil (palm butter-fat, etc.).
Palmkernel oil and fat.
Cocoon oil fat and tallow.
Vegetable tallow.
Vegetable Ivory.
Oleic.
Margarine.
Edible vegetable tallow.

VII.—ANIMAL PRODUCTS

Egg-yolk.
Egg-albumen.
Bees and other insect waxes, honeycombs.
Spermaceti.
Fish glue, agar-agar.
Glue-wish.
Bones, horns, hoofs, etc., not for cutting purposes.
Horn-waste for fertilizer.
Bone and other animal blacks; bone-ash.

VIII.—STARCH, SUGAR

Potato starch, green or dry.
Rice starch.
Corn, wheat and other starches.
Starch, gums, dextrins, burnt starch, paste, adhesives and gluten-meal.
Cane sugar.
Beet sugar.
Beet sugar, flats, sticks and cubes.
Beet sugar, ground.
Beet sugar, lump.
Beet sugar, ground refined.
Beet sugar, loaf.
Beet sugar, brown.
Beet sugar, confectioners.
Cane sugar, raw, solid or liquid.
Beet sugar, raw, solid or liquid.
All other solid and liquid sugars.
Sirups and molasses.
Starch, fruit and other fermentable sugars, burnt sugar.
Caramel, solid and liquid.
Invert sugar.
Milk sugar.

IX.—ALCOHOL, VINELAR, YEAST AND MINERAL WATER.

Alcohol, in barrels.
Alcohol, in bottles.
Vinegar of all kinds.
Methylated spirits.
Wine yeast.
All other yeasts.
Mineral waters, artificial, etc., incl. bottles.

X.—MINERAL AND FOSSIL RAW MATERIALS

Alumite.
Clay, common, potters', fire and pipe.
Kaolin and china clay.
Burnt clay, chamotte, Fayenc, etc.
Yellow, ochre, bole, Sienna and Verona carths.
Other earth-colors, artificial oxide iron, crude.
Chalk, white, crude.
Graphite, crude, ground and washed.
Pumice, Tripoli, crude, ground, washed or in bricks or tile.
Emery, crude, ground or washed.
Mineral abrasives, polishes and cleansers, crude, ground or washed.
Enamel and glasses.
Kieselguhr, quartz-sand, fire-stones.
Lime, slaked, limestone or lime mortar.
Magnesia.
Manganese, native or burnt.
Witherite, native or burnt, strontianite.
Lime phosphates (Apatite, phosphorite, coprolite, etc.).
Gypsum; kypsum—superphosphate.
Puzzolan, etc.
Portland and Roman cements.
Ground lime; tripolith.
Asbestos, crude.
Venetian chalk, crude, ground or burnt.
Talc, crude, ground or burnt.
Mica, crude.
Tin oxides and Cobaltite.
Feldspar, ordinary.
Fluorapatite, crude; Kryolite, natural.
Bauxenite and Tinsel.

Monazite-sand.

Falters and other earths and bituminous shale.

XI.—ORES, IRON, SLAUGS

Antimony ore and matte.
Antimony regulus.
Arsenic ores.
Lead ore.
Chrome ore.
Iron ores.
Gold ores.
Copper ores, inclusive of pyrites cinders.
Copper regulus.
Manganese ores.
Nickel ores.
Platinum ores.
Pyrites (Pyrrhotite, marcasite, etc.).
Silver ores.
Tungsten ores.
Zinc ores.
Tin ores.
Uranium, molybdenum and other ores n. s. p. f.
Gas-purifying masses containing iron or manganese; slags, slag felts, slag wools; ferrovanadium, sedge; ashes, pyrites-cinder, etc.

XII.—FOSSIL FUELS

Anthracite, bituminous and canal coal.
Lignite.
Peat-coke and peat fuels.
Coke.
Coal briquettes.
Lignite—briquettes.
Coke-like residues and artificial fuels.
Carbons, formed and crude; vegetable carbon.

XIII.—MINERAL OILS AND OTHER FOSSIL RAW MATERIALS

Lubricating and vaseline oils.
Crude petroleum; pitch and natural liquid asphalt.
Heavy gaselines, turpentine substitutes.
Gas oils.
Refined petroleum.
Crude gasoline.
Benzine, gasoline, ligroin, petroleum ether and similar refined light-oils.
Lignite, peat and shale-oils and other not otherwise specified mineral oils, tars and pitches.
Paraffine, crude and refined.
Soft paraffin.
Solid asphalt and asphalt bricks.
Asphalt-mastic, pitch, resin and wood cement.
Ozocerite and mountain-pitches, crude.
Refined ozocerite, ceresin.
Pitch and black wax.
Pitch-like petroleum residues heavier than water.
Shale-pitch; lignite tar, peat-tar, wood tar, birch tar.
Oil and water-gas tar.

XIV.—COAL, TAR, OILS AND PRODUCTS

Coal tar.
Carbolineum.
Coal tar pitch.
Resol, laboul, cumol, etc.
Anthracene, carbolic, cresosol and other heavy coal-tar oils and asphalt-naphtha.
Solvent-naphtha.
Naphthalene.
Anthracene.
Phenol, crude or refined.
Lime carbolate.
Pyridine bases.
Cresol, crude carbolic 100 per cent.
Anilin, oil and salts.
Isosulphuric acid.
Benzol chloride.
Naphthol, naphtholene.
Naphthol compounds.
Anthrachinone, nitrobenzol, Toluclidia, Resorcin, Phthalic Acid and other coal tar products.

XV.—WAXES

Prepared bees and other insect waxes.
Prepared vegetable waxes.
Vegetable wax waste.

XVI.—SOAPS AND FAT PRODUCTS

Ordinary soft soap; oils and fluid fats; Turkey red oil; liquid Creolin and like cleansers, soap substitutes in barrels.
Hard soaps. Creolin and like hard cleansers; soap substitutes and evaporated lyes not elsewhere specified.
Cake-soaps; liquid soaps, soap powders, papers and other soap substitutes.
Stearin, palmitin.

Tapers, candles and night-lights.

Photograph plates and rolls of wax or ceresin.
Crude glycerin.
Refined glycerin.
Soap waste lyes.
Paraffin ointment, vaseline, vaseline ointment, lanolin and lanolin preparations.
Rosin-soaps.
Degras.
Acid-crease.
Other lubricants made from fats or oils.
Shoebuckling, solid.
Yellow shoe polish.
Polishes made of fats, oils, soaps, alumina soap, artificial polishes.
Stearin, palmitin, etc., formed.

XVII.—CHEMICAL AND PHARMACEUTICAL PRODUCTS

Abram Salts:
 12-15 per cent K_2O , more than 15-19 per cent K_2O .
Abram Salts N. S. P. F.
Acetates, all other n. s. p. f.
Acetone oil.
Acid:
Acetic.
Acetylsalicylic.
Arsenic.
Arsenious.
Benzoic and sodium benzoate.
Boric.
Chlorosulfonic.
Citric.
Formic.
Hydrochloric (nitrohydrochloric).
Hydrofluoric.
Lactic.
Nitric.
Oxalic.
Phosphoric.
Salicylic and sodium salicylate.
Sulfuric:
 Non-fuming.
 Fuming.
 For fertilizers.
 Spent.
 Tannic and gallic.
Tartaric.
Acid, Anhydrides.
Acetic.
Sulfuric.
Alkaloids and other metals not specified.
Alkaloids, all other, their salts and compounds.
Alum.
Soda, potash or ammonia.
Chrome, iron or copper.
Aluminum:
Acetate.
Chloride.
Hydrate, artificial.
Oxide, artificial.
Sulfate.
Sulfite.
Sulfocarbonate.
Ammonia water.
Ammonium:
Carbonate.
Chloride.
Fluoride.
Nitrate.
Sulfate.
Ammonium compounds, not dyes.
Antimony:
Fluoride.
Oxalate.
Regulus or metal.
All other compounds n. s. p. f.
Are Carbon.
Argols, crude or refined (soda or potash).
Artificial and natural mineral water salts.
Artificial balsams, extracts and waters, not perfumes.
Arsenic:
Metal.
Sulfide.
Compounds, all other n. s. p. f.
Barium:
Chloride.
Chloride.
Hydrate.
Oxide.
Nitrate.
Peroxide.
Sulphide.
Beetroot Potash.
Benzonates n. s. p. f.
Bismuth salts.
Borne.
Brom or
Bromides of potash, soda, and iron.
Bromides n. s. p. f.
Bromoform and Iodoform.
Bromine organic compounds.
Bromine n. s. p. f.
Caffeine.
Calcium:
Carbide.

Ammonia nitrate	Wool grease	Bichromate	Wool grease
Ammonia perchlorate	Turkey red	Borate	Borate
Apatite	Linseed	Carbonate	Carbonate
Argois	Poppy seed	Sul	lithyl
Crude tartar	Rape seed	Sulfate crystals	lithyl
Rochelle salts	Peanut	Tarum	Palm kernel
Calcium tartrate	Hamseed	Ground tale	Stearite
Balsams:	Almond, sweet	Stearite	Soya bean
Copaiba	Sesame	Vanilla	Olive oil
Fir	Bean	Vanilla	Chinese nut
Canada	Olive	Vanilla beans	Nut
Feru	Orange	Tonka beans	Kerosene
Tolu	Lemon	Arsenic	Naphtha
Barium chloride	Peppermint	Sulfide of arsenic	Paraffine
Dioxide	Almond, bitter	Cinchona bark	Whale
Carbonate, precipitated	Anise	Bauxite	oleo-stearin
Blacking, polishing powders and creams	Ambergris	Bauxite	ores of gold
Bleaching powder	Anise	Bismuth	Silver
Caffin	Bergamot	Copper sulfate	Nickel
Calomel	Camomile	Acetate	Platinum
Corrosive sublimate	Camomile	Sub-acetate	Paris Green
Chalk, precipitated	Cassia	Bone dust	London Purple
Chloral hydrate	Cinnamon	Meal	Phosphates, crude
Satol	Cedra	Ash	Phosphorus
Phenolphthalein	Citronella	Crude	Photographic films
Urea	Lemongrass	Borates of soda, crude	Plumbago
Terpin hydrate	Civet	Lime, crude	Potash:
Acetanilid	Fennel	Bromine	Crude or black salts
Acetphenetidine	Jasmine	Cadmium	Carbonate
Antipyrine	Juniper	Calcium acetate, brown or gray	Sulfate
Glycero-phosphoric acid	Lavender	Calcium chloride, crude	Hydrate
Acetilsalicylic acid	Aspic	Calcium carbide	Nitrate
Aspirin	Limes	Calcium nitrate	Quinine Sulfate and all cin-
Guaiac carbonate	Neroli	Cement, Roman, Portland and other hydraulic	chona alkaloids
Thymol	Urganum (red and white)	Cerium ore	Radium and its compounds
Chloroform	Thyme	Chromate of iron	Selenium and its salts
Carbon tetrachloride	Valerian	Chromium, hydroxide, crude	Salt
Benzo	Morphine sulfate	Anthracene	Santonin
Naphthol	All other opium alkaloids	Anthracene oil	Sheep dip
Resorcin	Cocaine	Naphthalene	Soda arsenate
Toluol	Ecgonine	Phenol	Cyanide
Xylol	Barytes	Cresol	Sulfate (salt cake)
Toluidin	Blanc fixe	Cobalt and ore	Bi-sulfate (niter cake)
Xylidin	Satin white	Cochineal	Ash
Cuminid	Blues:	Sulfate of iron	Silicate
Nitrobenzol	Prussian	Cryolite	Nitrate
Binitrotoluol	Berlin	Cudbear	Soda bicarbonate
Benzidin	Chinese	Dividivi	Strontium oxide
Tolidin	Ultramarine	Fulminates	Carbonate
Dianisidin	Black:	Gambier	Styechine and its salts
Naphthylamin	Bone	Gambier	Sulphur
Diphenylamin	Ivory	Greases and fats for soap making	Pyrites
Benzaldehyde	Vegetable	Guano	Talcum, stearite, French chalk
Benzylchloride	Gas	Basic slags	Tanning extracts:
Nitrobenzol	Lamp	Chrome:	Ambrachio
Nitrotoluol	Cyanamide	Yellow	Hemlock Bark
Naphthylamin sulfo acids	Green	Lime-nitrogen	Oak
Naphthol sulfo acids	Ochre	Gunpowder and all explosives	Chestnut
Amidosalicylic acid	Sienna	Gutta percha	Nuts
Binitrochlorobenzol	Umber	India rubber, crude, scrap and refuse	Nutgalls
Diamidostilbendi sulfo acid	Spanish brown	Indigo	Terra alba
Metanilic acid	Venetian red	Iodine	Tin ore and metal
Paranitronilin	Indian red	Iridium, osmium, palladium, rhodium and ruthenium	Tungsten ores
Dimethylaminilin	Colcothar	Iron ore	Turpentine, Venice and spirits
Colbalt, oxide of	Litharge	Kieserite	Uranium oxides and salts
Colloidon	Orange, mineral	Kainit	Valonia
Ethers:	Red lead	Casein	Waxes vegetable or mineral
Sulfuric	White lead	Lard	Witherite
Amyl nitrite	Lead acetate	Asphalt, bitumen	Woodpulp:
Amyl acetate	Lead nitrate	Litmus	Mechanical
Ethyl acetate	Varnishes	Madder	Chemical
Ethyl chloride	Vermilions	Magnesite	Bleached
All other ethers and esters	Whitening and Paris white	Manganese, oxide and ore of	Unbleached
Extracts of:	Zinc oxide	Myrobolans	Metalles
Nutgalls	Lithopone	Oils:	
Persian berries	Zinc sulfide (white)	Birch tar	
Sumac	Zinc chloride	Cajeput	
Logwood	Zinc sulfide	Cocoonut	
Chlorophyll	Enamel paints	Cod	
Saffron	Paints		
Safflower	Colors		
Formaldehyde	Stains		
Fusel oil	Pigments		
Amylic alcohol	Crayons		
Gelatine	Smalts		
Glue	Ceramic fluxes		
Glue-size	Glass fluxes		
Isinglass	Potash:		
Agar-agar	Bicarbonate		
Glycerine, crude	Chlorate		
Glycerine, refined	Chromate		
Gum:	Bichromate		
Amber	Nitrate		
Arabic	Permanganate		
Senegal	Red prussiate		
Camphor, crude	Yellow prussiate		
Camphor, refined or synthetic	Salts of bismuth		
Chicle, crude	Gold		
Dextrine	Platinum		
Burnt starch	Rhodium		
British gum	Silver		
Ink and ink powders	Tin

indexed, and to have them accompany the final recommendation when and if it is presented to the officials in Washington. The work of the members of the local sections of the chemical societies and of this special committee will be greatly expedited if each such letter were to be accompanied by seven carbon copies to serve as working copies for the various committee members, and such effective co-operation will be more than repaid in speed and certainty.

The final recommendation of this special committee must be backed up, so far as possible, by individual letters, otherwise those recommendations might very properly be looked upon as the personal opinions of only a few; that would not be fatal, but it would be disadvantageous.

This special committee itself cannot possibly bring this plan to the attention of all interested; it must depend upon the co-operation of the members of the national chemical societies to bring this matter to the attention of local boards of trade, chambers of commerce or similar co-operative business organizations, and to the attention of individual concerns and corporations. Each member has his work to do, and this special committee counts with entire confidence upon a full performance.

Persons and corporations not members of a chemical society need feel no hesitancy whatever in taking active part in this work; write your suggestions to the secretary of the section of the A. C. S. or A. E. S. nearest to you. There are no formalities and there is no need to stand on ceremony.

With 55 centers of information-gathering located in 32 states of the Union and the District of Columbia a substantial consensus of opinion should be obtainable.

In addition to the foregoing list helpful suggestions may be obtained by consulting the weekly import and export lists that appear in the *Oil, Paint and Drug Reporter* of New York, and the daily lists of manifests of incoming steamers as they appear in the *Journal of Commerce and Commercial Bulletin* of New York; also the weekly and annual summaries of British foreign and domestic chemical trade as they appear in *The Chemical Trade Journal* may offer useful suggestions.

List V gives the name and address of the secretary of each local section of the A. C. S. and of the A. E. S., arranged alphabetically by States.

Should there be any changes in local secretaries from the list above given, the person addressed as above can be confidently counted on to forward such communication to his successor.

The present plan is for this special committee to begin its preliminary list Nov. 1, 1916, complete it Nov. 15, 1916, publish this provisional list in the *METALLURGICAL AND CHEMICAL ENGINEERING* Dec. 1, and *Journal of Industrial and Engineering Chemistry*, Dec. 6, 1916, begin its final draft Feb. 14, 1917, close the final recommendations Feb. 28, 1917, and present its recommendations to the proper authorities in Washington before March 15, 1917; this will leave three and one-half months for Washington to make its decision and arrange for the gathering of the added information, if any, decided upon with the beginning of the fiscal year 1917-1918.

Delay or failure in getting suggestions to the local sections will hamper the special committee. Points of view cannot be considered unless communicated. Everybody's co-operation is not only necessary, but most cordially invited. If our list is not the best in the world to-day we must strive to make it so.

25 Broad Street,
New York City.

Fire-Resisting Materials—The Bureau of Standards, Department of Commerce, in connection with a general study of fire-resisting materials, is considering among other phases of the subject the development of a fire-resisting material for use in constructing, in whole or in part, the deck structures of excursion and passenger steamers. So far as may be applicable, the material when developed would also be considered in relation with other marine uses. The Bureau of Standards would be glad to receive from manufacturers samples of such materials as they consider suitable for the purpose, in order that they may be given consideration.

An Investigation Dealing with the Occurrence of Alumina Inclusions in Steel

BY ALBERT SAUVEUR

NATURE OF INCLUSIONS IN STEEL

By the term "inclusions" (or "enclosures"), the steel metallurgist refers to small particles of non-metallic and generally oxidized impurities mechanically held by steel after it has completely solidified. These inclusions are as a rule lighter than the metal in which they are imprisoned, and if the latter could be kept liquid for a sufficient length of time after their formation most, if not all, of these foreign particles would rise to the top of the ingot or casting. Owing to the very small size of some of them, however, and to conditions of manufacture, a small amount of these inclusions must of necessity be retained in the solidified metal.

The inclusions commonly described comprise silicates, chiefly of manganese and of iron (frequently called "slag"), and manganese sulphide (often associated with iron sulphide). The use of titanium as a deoxidizer may introduce some titanium nitride inclusions, while the use of aluminium for the same purpose may result in the formation of alumina inclusions through the oxidation of some of the aluminium.

PURPOSE OF THE INVESTIGATION

The present investigation was undertaken for the purpose of ascertaining whether the occurrence of alumina inclusions in steel could be detected under the microscope and of studying the characteristics by which these inclusions can be distinguished from other inclusions.

PAST LITERATURE

Barring one or two unimportant exceptions, I am unable to find in the literature dealing with inclusions any reference to the occurrence of alumina antedating Mr. Comstock's article presently to be described. Previous to his writing, alumina had not generally been considered as a distinct or, at least, as a distinguishable inclusion.

Referring to the use of aluminium as a deoxidizer, however, and to the resulting formation of alumina, Rosenhain¹ writes:

"A more powerful deoxidizing agent than manganese is furnished by aluminium, but this differs from manganese in two vitally important respects. In the first place, the oxidation product of aluminium is a particularly refractory substance—alumina—which has a strong tendency to remain in the molten metal in suspension as fine particles."

In a paper entitled "The Solid Non-Metallic Impurities in Steel," the author, Mr. Henry D. Hibbard, writes:

"If other elements have been added, such as Al, W, Cr, Ti, or V, their oxides and silicates may be present.

"The too plentiful use of Al in steel may have been condemned, partly at least, because it forms oxides or silicates in the metal, which, being insoluble and infusible, exist in the solid steel as very harmful sonims. Of course, to form the oxide there must still be some oxide of iron or manganese in the steel. If the metal were free from O perhaps the weakening effect of Al when added in greater quantity than a few hundredths of 1 per cent would not occur. So a part of the Al added in the ladle would form sonims which might be fluxed and floated out, while that added in the molds, if the steel were free from O, would not be oxidized, but would all be left to exercise its full effect in preventing the formation of gas-bubbles and the resulting blow-holes in the steel."

MR. GEORGE F. COMSTOCK ON ALUMINA IN STEEL

In an article entitled "A Study of Alumina in Steel,"

published in METALLURGICAL AND CHEMICAL ENGINEERING for Dec. 1, 1915, Mr. George F. Comstock describes the occurrence and appearance of alumina inclusions in steel. Referring to alumina inclusions, Mr. Comstock writes:

"These inclusions are in the form of small rounded spots, arranged close together in one elongated streak. They are of a very dark bluish-gray color, when examined with the white light of an electric arc, appearing black unless highly magnified, and it is practically impossible to polish them without forming little pits around each inclusion. If the polishing is done very carefully, these pits may be kept very small; but with certain methods of polishing the pits are made so large that the original inclusions cannot be seen at all.

If the specimen is not rotated constantly during the final polishing, the pits take the form of short scratches, and each inclusion will have a little tail, like a comet. It will be noticed in Fig. 1 that although this shows a longitudinal view of a bar, the individual inclusions have not been elongated by the forging at all, but merely the group as a whole has been drawn out into a streak.

"The difference between inclusions of alumina and ordinary slag or silicates in steel may then be summarized as follows:

"(1) Silicate inclusions will generally take a fairly smooth polish in a section prepared for microscopic examination, while alumina is very hard to polish without pitting. (2) Silicate inclusions are always elongated in the direction of rolling or forging, while alumina particles are not (the groups of particles are, of course elongated but not the particles themselves). (3) Silicate inclusions are often found of quite large size (as well as very small), while particles of alumina are always small, and do not seem to coalesce into large bodies even when closely grouped together. These characteristics of alumina inclusions agree with what is known of the properties of alumina. Its great hardness and brittleness would account for the pitting effect; its infusibility would account for the small size of the particles and the tendency not to coalesce; and both of these properties together would account for the particles not being elongated by forging or rolling of the steel in which they were embedded.

"All samples in which more than the merest trace of alumina was found by analysis were seen to contain the typical inclusions as described above, and those in which alumina was not found by analysis, did not contain these inclusions. Furthermore, those in which more alumina was found by analysis contained more of these inclusions than those in which only a very little was found. These facts have been considered as a good confirmation of the theory that the typical small inclusions, as described above, found in so many commercial steels, are chiefly, if not wholly, alumina."

INVESTIGATION

As a preliminary step I took photomicrographs at a magnification of 300 diameters of five samples that Mr. Comstock used in his work, and a comparison of these photomicrographs with those taken by him showed that both sets were very similar and that they confirmed Mr. Comstock's description of the appearance of the inclusions.

In Fig. 1 is shown under a magnification of 300 diameters the appearance of the longitudinal section of a bar forged from a steel ingot to which 0.144 per cent aluminium had been added during the teeming from the ladle to the molds. The steel was made at the Watertown Arsenal, Watertown, Mass., in a Tropenas converter. Both ferro-manganese and ferro-silicon were used in recarburizing and deoxidizing. The inclusions shown in the photomicrograph present the characteristics described by Mr. Comstock as pertaining to alumina inclusions, namely, small dimensions of the individual particles, dark coloration, string formation in the direction of the forging, but non-elongation of the particles themselves.

Attempts were made as follows to produce molten iron under such conditions as to preclude the occurrence in the solidified metal of any inclusions but alumina:

¹An Introduction to the Study of Physical Metallurgy, Walter Rosenhain, page 153.

²Transactions of American Institute of Mining Engineers, Vol. XLII, pages 803-822.

1. Thermit iron produced with an excess of aluminium.

2. Ingot iron melted with aluminium.

3. Ingot iron melted with alumina.

The results obtained will be briefly described.

Thermit Iron.—A small mass of thermit iron was produced in the usual way in a graphite crucible with

the absence of elongation in the direction of the forging.

Ingot Iron Melted with Aluminium.—A small amount of ingot iron was melted in an alundum crucible with the addition of aluminium. The expectation was that enough oxygen would be present to cause the oxidation of some aluminium and, therefore, the occurrence of alumina inclusions to the exclusion of all other inclu-

FIGS. 1 AND 2—MICROPHOTOGRAPHS

the addition of a small amount of finely powdered aluminium to the thermit mixture as commercially supplied. The small ingot was forged into a bar about $\frac{1}{4} \times \frac{1}{4}$ in. in cross-section.

It is believed that the thermit mixture practically consists of pure iron oxide and pure aluminium, and that any inclusions present must of necessity be alumina resulting from the oxidation of some aluminium.

A longitudinal section of the forged bar was prepared for microscopical examination and the polished but unetched surface photographed under a magnification of 300 diameters (Fig. 2). It will be seen to contain many small, dark and roughly rounded particles scattered

sions. The resulting mass was forged into a bar measuring about $\frac{1}{4} \times \frac{1}{4}$ in. in cross-section. A longitudinal section of the bar was polished and photographed under a magnification of 300 diameters. The presence of a number of small dark particles was clearly revealed (Fig. 3). They exhibit the characteristics previously described as pertaining to alumina inclusions, being small in size, dark in color, and non-elongated in the direction of the forging.

Ingot Iron Melted with Alumina.—Some ingot iron was melted in an alundum crucible with finely powdered alumina. It was assumed that while most of the alumina might float to the top of the molten bath, some of the

FIGS. 3 AND 4—MICROPHOTOGRAPHS

through the iron. It should also be noted that there is no indication whatever of these inclusions having been elongated by the forging. Although they do not occur in clusters or in strings, they present the chief features described by Mr. Comstock as characteristic of alumina inclusions, the most significant of which is

finest particles at least would be retained in the solidified metal as alumina inclusions. The small ingot was forged into a bar $\frac{1}{4} \times \frac{1}{4}$ in. in cross-section, and the appearance of a longitudinal section polished and magnified 300 diameters is shown in Fig. 4. Here again we note the occurrence of small dark inclusions scattered

through the mass and devoid of any tendency to elongate in the direction of the forging.

SUMMARY

From the results published by Mr. Comstock and confirmed by my examination of some of his samples, and from the results obtained in my own experiments as reported in the foregoing pages, it seems justifiable to conclude that alumina inclusions may be distinguished under the microscope from the other inclusions generally occurring in steel, being characterized by their small size, their dark coloration, and more especially by a complete absence of elongation in the direction of the rolling or forging.

Harvard University, Cambridge, Mass.

Synthesis of Tartaric Acid

The synthesis of tartaric acid is the subject of a patent of Dr. L. H. Baekeland and Arnold H. Peter (U. S. Patent 1,190,845, July 11, 1916). The process which is shown diagrammatically in Fig. 1 involves seven reactions marked respectively A, B, C, D, E, F, G. We quote the following description of the process from the patent specification.

(A) Carbon in any form, for instance, coke or charcoal, is introduced into a chamber or vessel provided with heating means. Into this vessel is conducted a colorless mixture of chlorin (which may be obtained later on in the process from reaction described in B or D or E or all of them) and water, preferably in the form of steam. When this mixture is conducted over the carbon heated to about 300 deg. C., there results hydrochloric acid and carbon monoxid or carbon dioxide or a mixture of the two carbon oxids. In ordinary practice, a mixture of the two oxides will result, it being usually not worth while to attempt to confine the production exclusively to either one. The hydrochloric acid thus obtained may be used in some of the reactions herein-after described either to promote said reactions or recover chlorid from their results, or both. The carbon-oxids may be used in making formates, as hereinafter described in B. Commercial requirements will determine whether both the acid and the carbon-oxids shall be used in succeeding reactions or one of them disposed of otherwise.

(B) From the carbon-oxids formate may be obtained in a variety of ways. For example, the mixture of carbon monoxid and carbon dioxide may be conducted over carbon heated to about red heat, reducing the carbon dioxide in the mixture to carbon monoxid, and the carbon monoxid may be conducted over an alkali (such, for example, as caustic soda, caustic potash, or others) heated to, say, 180 deg. to 220 deg. C., giving a formate. Or the carbon dioxide may be reduced to formate in a way which in itself affords an illustration of the process of the present invention.

Thus, water in a reaction chamber may be saturated with carbon dioxide (or the mixture of carbon-oxids containing it) and an amalgam, preferably produced by the electrolysis of a chlorid, may be caused to travel into such chamber, where it liberates hydrogen, reducing carbon dioxide to formate.

It will be observed that when this method is followed the reactions embrace the electrolysis of a chlorid, giving chlorin and a reducing agent, the utilization of the chlorin to assist in oxidizing a substance and the reduction of the oxidized substance by the reducing agent.

The hydrochloric acid resulting from the use of the chlorin with water (in the form of steam) to oxidize the carbon may be used to attack the amalgam, throw off the hydrogen from it for the reduction of the carbon dioxide and unite with the amalgam to form chlorid.

It may under some circumstances be desirable to use this cycle of chlorid, chlorin and amalgam, hydrochloric acid from chlorin, decomposing the amalgam to form chlorid and give off hydrogen, to reduce carbon dioxide obtained elsewhere.

For example, it may be, under certain circumstances, desirable to make the chlorin react upon the carbon in the presence of water or steam so as to produce hydrochloric acid and carbon monoxid almost exclusively (which may be made in this manner of exceptional purity) and dispose of the carbon monoxid, ob-

FIG. 1—SYNTHESIS OF TARTARIC ACID

taining the carbon dioxide to be reduced from some source not connected with the process.

The foregoing description of the reactions which have been designated B represents various ways of treating the substance oxidized with the assistance of the chlorin obtained from the chlorid or an equivalent substance so as to obtain formate. Any convenient way may be used. The further treatment of the oxidized product may be as follows:

(C) The formate may be transferred into oxalate in any convenient way, as by heating the formate to, say, 360 deg. to 440 deg. C., under pressure.

(D) The oxalate may be reduced to glyoxylate by means of an amalgam, preferably in an acid solution. This amalgam may be made by the electrolysis of a chlorid, preferably potassium chlorid, generating chlorin at the anode, which may be mixed with steam and conducted over carbon, as hereinbefore described in A.

The amalgam thus produced may be caused to travel into a reaction chamber containing the oxalate and an excess of hydrochloric acid which has been obtained by conducting the mixture of chlorin and steam over carbon, as hereinbefore described in A.

The amalgam, being attacked by the acid in this reaction chamber, gives off hydrogen, reducing the oxalate to glyoxylate, and, after giving off this hydrogen, combines with the hydrochloric acid to form chlorid, which remains in solution and may either be recovered at this point and again electrolyzed or allowed to pass with the glyoxylate into and through the transformation of the glyoxylate into tartrate, as hereinafter set forth.

It will be observed that the reactions described form a complete cycle, which may be summed up as follows:

Oxalate of sodium in presence of an acid gives oxalic acid. The latter in presence of potassium amalgam and a strong acid gives glyoxylic acid:

(E) The glyoxylate may be introduced in solution rendered alkaline into the cathode chamber of an electrolytic cell, the electrolyte in the anode chamber being preferably an alkali chlorid, although other soluble chlorids, even chlorid of hydrogen, may be used. When the current is caused to pass through the solution from the anode to the cathode the glyoxylate is reduced to tartrates (racemic and meso-tartrates), which are precipitated, used and worked up, as may be desired.

If, as above suggested, the chlorid resulting from the reaction D has been allowed to remain in solution with the glyoxylate, it may be recovered after the tartrates have been precipitated, as, for example, by evaporation.

The chlorin developed on the anode in this reaction may be used in accomplishing the oxidation of the carbon, the carbon-oxyds being used to produce formates, which may be converted into oxalates, which may be converted into glyoxylates, which may be converted into tartrates, as above indicated.

The alkali formed in the cathode compartment may be neutralized by the hydrochloric acid formed from the chlorin generated in the anode compartment.

The apparatus availed of in the process and in the various reactions will differ according to the particular circumstances of manufacture. In commercial practice, it will often be desirable, for example, to store temporarily the products of the various reactions, as, for instance, the formate or oxalate or acid or chlorid, before using them, or to connect the various sources of

chlorin so that the making of the hydrochloric acid or the oxidation or both may be conveniently accomplished.

The process contemplates that variations will be made in it according to commercial requirements. Thus, for example, in certain manufactures some of the reactions hereinbefore described may be omitted and the substances developed by such reactions obtained and introduced otherwise. For instance, a chlorid may be electrolyzed to develop amalgam and chlorin, the chlorin being used with steam and carbon to give hydrochloric acid and the acid used to liberate hydrogen from the amalgam and unite with the rest of it into chlorid, but instead of using the carbon-oxyds (which may be obtained in connection with the making of the acid) through reactions producing therefrom oxalates or oxalic acid, the carbon-oxyds may be disposed of otherwise and oxalic acid elsewhere obtained and introduced.

The invention has been described as embodied in a synthetic process for the manufacture of tartaric acids and their compounds from carbon, and it is pointed out that it is applicable also in the manufacture of certain compounds produced therein, as formates and glyoxylates. It is to be understood that it is applicable also in other synthetic processes.

It is particularly to be observed that in the specific embodiment of the invention applied to the manufacture of tartaric acids, the manufacture is conducted and the product obtained with practical freedom from by-products. The carbon of the coke or charcoal is caused to unite with the oxygen and hydrogen of the decomposed water, the cycle of reactions of the present invention supplying the principal ancillary substances necessary to accomplish this in such manner that practically no by-products are left.

The Hord Color Products Co., Sandusky, Ohio, are building a large dye factory. Dr. D. Julian Block of Chicago has been active in developing processes.

Bituminous Coal Output—The estimates made by the Geological Survey for the first six months of 1916 are interesting as they reflect the great industrial activity which is going on in this country at the present time. According to the estimates, the output was 261,000,000, tons or the largest output ever recorded for a half year period. This is an increase of 35 per cent over the first six months of 1915 and of 5 per cent over the last six months of 1915. The exports to Canada have increased considerably.

The Nordberg Mfg. Co., Milwaukee, Wis., has issued Bulletin No. 28, describing poppet valve engines of three types, viz., full poppet, poppet-uniflow and poppet-Corliss. For ordinary non-condensing service, the high-speed, full-poppet valve engine shows the highest efficiency. For condensing service two types of engines are offered—Nordberg poppet-uniflow and Nordberg poppet-Corliss, the former being an engine with uniflow cylinder design, that is, exhaust ports in the cylinder barrel and poppet steam valves, and the latter a compound engine with a full poppet high-pressure cylinder and a Corliss valve low-pressure cylinder. The poppet-uniflow engine is particularly adapted to widely fluctuating loads on account of its flat steam consumption characteristic. Recently two of the largest uniflow engines so far constructed in this country have been shipped to the Youngstown Sheet & Tube Co., for steel mill drive. The poppet-Corliss engine is adapted to constant load or constant m.e.p. work, under which conditions it shows very high steam economy. A compound engine of this type, fitted to an ammonia compressor, showed by test a steam consumption of less than 10 lb. per indicated horsepower-hour.

The Flotation of Oxidized Ores*

BY O. C. RALSTON AND GLEN L. ALLEN

Concentration of natural sulphide ores by the flotation process has met with such success that attempts have recently been made to apply the process to the flotation of ores other than natural sulphides.

As inquiries on this subject are frequently received by the Bureau of Mines, it has been thought best to publish a summary of the results so far obtained from the experimental work on oxidized ores at the Salt Lake City station of the bureau, in co-operation with the department of metallurgical research of the University of Utah. The work has been directed by O. C. Ralston, assistant metallurgist of the bureau, and was carried on for the most part by G. L. Allen. N. C. Christensen and R. W. Johnson also assisted with the work.

As above stated, this paper is only a summary, or a preliminary report of the experiments on the flotation of oxidized ores. More complete details as regards the flotation of carbonate ores of lead will be given by the writers in a paper on that subject, and in the near future the bureau expects to publish a still more complete discussion on the flotation of oxidized ores of lead, copper and zinc.

Most of the experimental work in the laboratory at the Utah station has been with the oxidized ores of lead. Only minor attention has been given to the oxidized ores of zinc and of copper for the following reasons: Little success has been had with the zinc ores; many others are engaged in testing copper ores, so that there was no pressing necessity of experimentation with copper ores by the bureau, although an attempt is being made to co-ordinate the work of those who are willing to co-operate to that extent.

Sulphidizing and Flotation of Oxidized Ores

Flotation of oxidized minerals depends upon a preliminary "sulphidizing" by any method that will convert at least the surface of the mineral particles to a sulphide of the metal. This step is followed by flotation of the "artificial" sulphide, which results in a concentration of the metallic values in the low-grade oxidized ore being treated.

The methods of sulphidizing that have been investigated are as follows:

Sulphidizing (1) by the use of hydrogen sulphide on either the dry or the wet crushed ore; (2) by the use of solutions of the various sulphides and sulfo-compounds of sodium; (3) by the use of solutions of the various sulphides and sulfo-compounds of calcium; (4) by the use of sulphur vapor; (5) by the use of a sulphureted oil; (6) with colloidal sulphur.

It has been found that treatment by some of these methods will form a film of sulphide over the surface of the particles of such minerals as lead carbonate or copper carbonate, whereas in other cases the mineral particles are sulphidized to the core. Other methods failed to give any results.

CARBONATE OF LEAD ORES

All of the above methods of sulphidizing have been tested on a great number of carbonate-of-lead ores. Some of these ores contained silver and some contained lead as the principal metal. A number of the ores have been successfully concentrated and others refuse to yield to concentration by flotation. In general, a high alumina content (acid soluble) in an ore seems to prevent the application of sulphidizing and flotation. The purpose of this report is to give the main features of the flotation of oxidized ores of lead, as well as other ores.

In sulphidizing with hydrogen sulphide gas, as applied to the lead carbonate ores, it was found that the best method of applying the gas to a dry powdered ore was in a tumbling barrel with the gas inlet in the end. Sulphidizing in a glass bottle showed that the ore blackened quickly after the application of the hydrogen sulphide gas. On attempting to float out lead sulphide from the ore as soon as it had blackened it was found that a low extraction of lead was obtained and likewise a low-grade concentrate, unless the pulp was previously acidified with sulphuric acid. By acidifying the pulp, cleaner concentrates were floated but the extractions of lead remained low. Only by prolonged treatment with hydrogen sulphide gas could the extraction of the lead be raised to commercial grade. With a number of ores eight hours' treatment gave an extraction of over 80 per cent of the lead.

The use of hydrogen sulphide was considered for the reason that it can be generated quite cheaply. With iron matte available at \$5 to \$10 per ton, and sulphuric acid from \$5 to \$10 per ton, the cost of the hydrogen sulphide resulting, including labor, etc., is between \$30 and \$50 per ton. If this gas in combining with the metal in the ore produces only a superficial film of sulphide, and does not penetrate to the center of the particles, it might be possible to make a ton of the gas sulphidize many tons of ore.

Unfortunately hydrogen sulphide attacks the metallic particles of the ore with such avidity that by the time the latter are sulphidized sufficiently to permit of good extraction by flotation, they have also been sulphidized to the core, and practically a chemical equivalent of hydrogen sulphide, to the lead in the ore, has been absorbed. Even coarse pieces of ore in a bottle absorb the gas with evolution of heat, and on breaking open the pieces the black coloration is seen to have traveled deeply into the particles.

Owing to the fact that the value of the lead concentrate obtained is very low as compared to the amount of hydrogen sulphide necessary to sulphidize it, this process is not regarded as commercially practicable.

Application of hydrogen sulphide to the ground ore suspended in water does not seem to be subject to the same difficulty. True "filming" of the particles with a film of lead sulphide seems to take place, and the extractions possible after a short treatment with the gas are satisfactory. The speed of travel of molecules of hydrogen sulphide gas, as compared with the speed of travel of the same molecules in solution affords an explanation of the difference in the action of the gas when applied to dry pulverized ore as compared to its action when applied to pulp suspended with water.

The best results on lead carbonate ores have been obtained when sulphides of sodium were used for the sulphidizing agent. The sodium sulphide must necessarily be introduced in solution and seems to cause true filming. The sulphides of sodium considered commercially applicable are the normal sulphide of sodium, Na_2S ; sodium polysulphides, Na_2S_x and Na_2S_y , and the sulphhydrate of sodium, NaSH . Of these the latter, the sulphhydrate, seems to be very effective, as is evidenced by the quicker blackening of the pulp, and the deeper, blacker color formed. The normal sulphide is almost as effective; the polysulphides seem to be the least active. Different ores require 10 minutes to 24 hours of contact with the solutions of sodium sulphide used, depending on the properties of the ore and on the strength of the solution of sodium sulphide. Amounts of sodium sulphide varying from 10 to 20 pounds per ton of ore are usually sufficient, and should be applied to pulp containing about one ton of water per ton of ore, in order that the solution may be as strong as possible during

*A report issued by the Bureau of Mines, under the direction of the Director.

the sulphidizing stage of the process. After a good black color has developed, and the color has ceased to increase in blackness, the pulp is diluted with water to a 3:1 or 4:1 mixture and floated in either mechanically agitated or pneumatic machines. The market for sodium sulphide is limited, and it should be obtainable at considerably less than 2 cents per pound.

The polysulphide of calcium, obtained by boiling powdered sulphur with slacked lime, seems to be satisfactory for ores that yield easily to sulphidizing, but is sluggish in its action, as compared to the sulphides of sodium. The normal sulphide of calcium is only slightly soluble, and hence its use was discontinued as a possible sulphidizing agent. The sulphhydrate of calcium is the most active of these reagents, but has not been tested to any extent in this work, as there is doubt as to whether it would be commercially feasible to prepare such a compound.

Sulphidizing with sulphur vapor has been tried with little success, for the reason that it must be applied at a temperature above the boiling point of sulphur in order to prevent condensation of the sulphur. This means that the ore must be heated to a temperature above 445° C. There seems to be no difficulty in obtaining elemental sulphur vapor commercially, as pyrite will give up half of its sulphur content when heated in a closed space, and sulphur dioxide gas can be reduced to elemental sulphur by passing it through a heated zone in the presence of a reducing agent. As lead itself is easily reduced from its carbonate form, the temperature might as well be raised to the point where the lead can be liquated out, a reducing atmosphere being used instead of a sulphidizing atmosphere.

The use of a sulphureted flotation oil, in which loosely combined sulphur is available for combination with carbonates of lead or other metals, and the rest of the oil is then available for "oiling" the artificial sulphide, has given very little encouragement in the tests conducted by the bureau.

Finally colloidal sulphur, mentioned as a possible method of sulphidizing, does not seem to combine with lead carbonate at all. It floats as a white lining of the air bubbles in the flotation machine, and brings up very little lead with it.

Usually the precious metals contained in a lead carbonate ore accompany the lead. The writers have noticed that the silver extraction will lag behind the lead extraction when the ore is sulphidized with sodium sulphide, and that the reverse has usually been true when hydrogen sulphide was used.

The importance of sulphidizing flotation is due to the fact that there are many deposits of lead carbonate ore in all of the Western States, and many of these ores have been milled with varying success. Frequently the lead carbonate can be satisfactorily concentrated by gravity methods, but often it is found that the particles of lead carbonate go into the slimes and are lost. Tailing heaps containing 5 to 10 per cent of lead are common. The object of this investigation is to determine whether sulphidizing flotation could not be applied to the treatment of the deposits of lead carbonate above mentioned, to prevent the waste that now takes place when these ores are treated by gravity concentration processes, and render amenable to treatment carbonate ores that are too low grade to be treated by present methods.

The General Engineering Co., of Salt Lake City, Utah, has carried on extensive tests of different lead carbonate ores with varying success, according to the ore tested. The company owns several sulphidizing patents, which it has either patented or purchased.

A flotation plant to apply sulphidizing and flotation

to an ore containing lead, silver and gold is being constructed by the Prince Consolidated Mining Co. at Pioche, Nev., for the treatment of two tailing dumps from former pan-amalgamation and cyanide operations in that vicinity. This plant was expected to be in operation by July 1, 1916.

OXIDIZED COPPER ORES

Many attempts have been made, both by large operating companies and by other experimenters, to float the carbonate and other oxidized minerals of copper. For that reason the testing of such ores by the writers has been limited.

Hydrogen sulphide seems to be by far the best medium for sulphidizing oxidized copper ores previous to flotation. When applied to the dry ore, the writers found the same conditions as those mentioned for lead; the particles are sulphidized to the center, which requires an excessive amount of hydrogen sulphide. Applied to the wet pulp, the hydrogen sulphide seems to cause true filming. The writers' work has yielded black concentrates, but they are informed by Mr. Callow of the General Engineering Co. that the company has been able to reduce the amount of sulphur used to a point where the froth is green with slightly coated malachite. He states that as little as one-half pound of sulphur per ton of ore is giving good extractions in the plant of the Magma Copper Co., at Magma, Ariz., where his company has put in the first successful installation of this kind.

Sodium sulphide has been tested by a number of the larger companies who have some oxidized copper minerals in their sulphide ores. The amount of oxidized copper in such ores is usually a fraction of 1 per cent, so that two or three pounds of sodium sulphide per ton of ore are all that is necessary. This is usually added to the machines during flotation, or to the mixing tanks before flotation. The writers' experience is that if some little time of preliminary contact is allowed before flotation is attempted, better sulphidizing of the material will result.

Calcium polysulphide has been used for some time in a number of the large copper concentrating mills with indifferent success, and seems to be detrimental in some instances. On the ores tested by the writers fair results were obtained if the calcium polysulphide was allowed to act until the ore had become well blackened.

It is stated that sulphur vapor was tested at one of the large plants for flotation of oxidized forms of copper and gave better results than any other method of sulphidizing. Of course this method has the disadvantage of having to be applied to dried, heated and finely divided ore.

Sulphureted oils are being used at a number of plants to supplement other methods of sulphidizing and considerable secrecy is observed as to the technical details of this work.

So far as the writers know, colloidal sulphur does not assist in the flotation of oxidized forms of copper. Neither has the silicate of copper been successfully floated by sulphidizing flotation. It will blacken when sulphidized, but resists flotation. Possibly it still presents a silicate surface, rather than a sulphide surface to the flotation elements. For this reason a number of the large copper companies are seriously contemplating leaching the oxidized copper ores, rather than lose what silicate of copper may be present.

Repeated attempts to float the natural sulphides along with sulphidized minerals have failed, as the sulphidizing agents cause trouble with the flotation of the natural sulphides. By careful adjustment this difficulty has

been solved in one plant, though the details are not available.

OXIDIZED ZINC MINERALS

Attempts to float the oxidized particles of zinc from their ores, both before and after sulphidizing by most of the above methods, have met with no success whatever in the laboratory experiments of the writers. They are informed that some headway was made with the problem by Professor Traphagen, at the Colorado School of Mines, but that the sulphide film seemed to come off too easily. However, poor results were obtained, whatever the cause.

The writer's experience has been that most of the carbonate ores of zinc contain important amounts of the silicate, and this may be one reason for the non-success of this work, for the same reasons that copper silicate will not float.

Direct flotation of oxidized minerals of the kind mentioned, so far as known, has not been successfully accomplished. In all of the successful work witnessed by the writers there has been some form of alteration of the oxide to the sulphide. A number of parties claim to be successful in the flotation of copper carbonates without sulphidizing, and others in the flotation of scheelite, fluorite and magnetite. The authors were unable to verify these statements.

Results of Tests

Some of the best results and some average results which have been obtained in the work at the Utah station are given in the table following.

RESULTS OF SULPHIDIZING AND FLOTATION OF OXIDIZED ORES										
LEAD-SILVER ORE										
Ore No.	Source of Ore	METAL CONTENT OF ORE			METAL CONTENT OF CONCENTRATE			EXTRACTION		
		Lead, per Cent	Silver, Ounces	Gold, per Cent	Lead, per Cent	Silver, Ounces	Gold, per Cent	Lead, per Cent	Silver, per Cent	Gold, per Cent

METHOD OF SULPHIDIZING

Ore 1.—Two hours' treatment with H_2S gas on dry ore.

Ore 2.—Four hours' treatment with H_2S gas on dry ore.

Ore 3.—Eighteen hours' treatment with 1 per cent solution of Na_2S , 20 lb. per ton of ore.

Ore 4.—Three hours' treatment with 0.8 per cent solution of CaS , 16 lb. per ton of ore.

Ore 5.—Four hours' treatment with 1 per cent solution of Na_2S , 20 lb. per ton of ore.

Ore 6.—One-half hours' treatment with 6 per cent solution of Na_2S , 12 lb. per ton of ore.

Ore 7.—One-half hours' treatment with 0.75 per cent solution of Na_2S , 15 lb. per ton of ore.

Ore 8.—Short-time treatment with hot 1 per cent solution of Na_2S , 20 lb. per ton of ore.

Ore 9.— Na_2S or H_2S in various amounts.

PATENTS ON SULPHIDIZING AND FLOTATION PROCESSES

A list of patents dealing with methods of sulphidizing and flotation follows:

U. S. Patent	807,501	June 1, 1915	H. C. Bacon
U. S. Patent	1,094,760	April 29, 1914	H. C. Bacon
U. S. Patent	1,095,668	May 25, 1915	H. C. Bacon
U. S. Patent	1,140,885	May 25, 1915	H. C. Bacon
U. S. Patent	1,140,966	May 25, 1915	H. C. Bacon
U. S. Patent	1,159,942	Nov. 9, 1915	H. C. Bacon
U. S. Patent	1,180,816	April 25, 1916	H. C. Bacon
British Patent	26,019	Nov. 10, 1909	H. C. Bacon

(Note.—Provisional specifications 28,612, Sulman and Picard, applied for Dec. 7, 1909, and 29,616, applied for Dec. 17, 1909, are incorporated in British Patent 26,019.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Gold Dredge.—What is reported to be the largest ladder dredging unit thus far constructed is described in *Engineering Record*, June 24. The hull was launched at Hammonton, Cal., in April. It is equipped with an endless chain of 100 buckets, each of 16 cu. ft. capacity. Material is to be excavated from a depth of 82 ft. below water level. The monthly capacity is 300,000 cu. yd. of material, and this yardage is handled with a crew of but three men. The dredge is operated by a 400-hp. motor for driving the excavator, and six other motors ranging from 35 to 150 hp. The hull is built of structural steel and weighs about 1000 tons without mechanical equipment. This dredge is to be operated on the Yuba River by the Yuba Consolidated Gold Fields Company, and is to be duplicated by a sister dredge to be launched this fall.

Copper

Dust Losses at Copper Queen Reduction Works.

In an elaborate paper prepared by Mr. J. MOORE SAMUEL of Douglas, Ariz., for the September meeting of the American Institute of Mining Engineers, the author gives the results of measuring dust losses from blast furnaces, converters and roasters at the Copper Queen smelter. The following essentials of a suitable method for determining such losses are laid down:

1. The sample of gas taken for filtration must be representative of the whole volume of gas, that is to say, it must have the same dust content. This condition will be fulfilled in all cases if the gas sample is drawn off without change of rate of flow. Then it will contain the same proportion of entrained or suspended particles of dust as the original gas. In the case of flue gases which contain only fume, at a temperature above or near the sublimation point, this condition need not be adhered to since the fume will not behave as entrained particles, but more nearly as a true gas. Consequently the gas sample in this case only may be drawn off at any rate of flow.

2. The gas sample taken must be large enough (a) to yield sufficient dust to permit of accurate chemical and physical examination; (b) so that the ratio of the total volume of gas passing through the flue to the volume of gas sample taken, shall not be too large.

3. The methods of measurement of gas volumes should be such that an occasional independent check can be made.

After describing in some detail the methods employed, which can be best obtained from the original paper and the tabulated results and drawings, the author gives some condensed data on the improvements secured through changes in practice suggested by the tests.

In 1909 when the tests were started, the equipment consisted of five 42 x 240-in. and five 42 x 216-in. blast furnaces and eight acid-lined converters of barrel type, 8 x 11 ft. Following these original tests an experimental settling chamber of 23 sq. ft. cross-sectional area and 50 ft. long was erected to make tests of dust settling at different rates of gas flow. Later this test chamber was lengthened to 100 ft. As a result of the experiments it was concluded that flues or settling chambers need not be longer than 125 ft. if the gas velocity did not exceed 150 ft. per minute, and that this velocity could be exceeded if wires or screens were placed in across the direction of flow. The dust chamber was subsequently enlarged to conform to these conclusions, and further tests were made. Comparing the results obtained with previous tests made under the same operating conditions, there is a decrease in dust loss of 103,800 lb. per day (from 164,680 to 60,860), and in the copper loss of 10,800 lb. per day (16,142 to 5355). That is a decrease of 63 per cent of dust loss and of 67 per cent of the copper loss.

In 1913, after the reverberatory and roaster plant had been blown in, the fine ore was no longer charged into the blast furnaces. Another series of tests was made under these conditions which shows a further decrease, the dust loss being 40,000 as against 60,000, and the copper loss 2589 as against 5355. It should be noted, however, that one less blast furnace was in operation.

Reverberatory dust losses are probably nominal and have not been determined.

The roaster losses have been determined under the following different conditions of operation:

Roasters in Operation	Draft	Feed
1	Low	Fine
2	Mixed	Mixed
3	High	Mixed
4	Low	Mixed
(5)	Low	Coarse

The roaster plant consists of sixteen six-hearth McDougall roasters, 18 ft. in diameter. The flue is 144 ft. long with a free cross-sectional area of 1235 sq. ft. Wires are hung in all but the first and last 12 ft. of the flue, or in a total length of 120 ft. From the tabulated results of roaster dust losses we note the following:

Roaster Feed	Tonnage of Charge Received in 24 Hr.	Dust Loss			Metal Loss in 24 Hr.			Draft at End of In- flue Dust Chamber Cubic Feet of Air per Minute
		Lb. per 24 Hr.	Per Cent of Charge	Grains of Dust per Cubic Foot of Gas	Gold, Oz.	Silver, Oz.	Copper, Lb.	
Pyrite	94	10,160	1.14	0.250		17.6	605	0.15 to 0.20
Pyrite and sulphate	752	52,704	3.508	0.894	0.75	101.7	4,388	0.21 to 0.28
Pyrite and sulphate	795	71,940	3.525	1.077	1.60	132.5	5,941	0.40 to 0.50
Pyrite	1,800	62,000	3.831	1.072	0.66	111.9	5,308	0.26 to 0.30
Sulphide ore	576	25,950	2.243	0.458	0.50	20.5	1,726	0.26 to 0.30

The roaster dust loss seems to depend on the tonnage treated by the roasters, the roaster draft, and the size of the particles fed. It is found in practice that the roaster draft has a great effect on the capacity of the furnaces, but our tests also show that increase of draft, or increase of tonnage treated, result in prohibitive dust losses, so that now the roaster draft is kept at

the absolute minimum which is required to carry away the gases.

Pumping

Pumping Costs with Diesel Engines.—Some interesting data on pumping water with Diesel engines is given by H. W. GOCHNAUER of Appleton, Wis., in the June 3rd issue of *Engineering Record*. For the year ended April 1, 1916, these engines pumped at an oil cost of \$2.82 per million gallons, against a head of 185 ft. The installation consists of two 225-brake-hp. three-cylinder, four-stroke Diesel oil engines. Each engine is direct-connected to two Deane double-acting triplex pumps of 2,000,000-gal. capacity each. In addition to pumping water the engines operated two 15-kw. 110-volt D.C. generators for lighting, without sensibly increasing the fuel-oil consumption. The operating labor consists of a chief engineer and three assistants, who work in two two-man shifts. For the year indicated the engines were operated 5948 hr., consuming 44,610 gal. of oil and pumping 569.43 million gallons of water. The fuel-oil average consumption per million gallons of water pumped was 78.6. Fuel oil cost 3.6c. per gallon, or \$2.82 per million gallons; lubricating oil, 36c.; labor, \$6.48; materials, \$1.98; total, \$11.64 per million gallons.

The efficiency of an air-lift is reported in the same issue of the *Engineering Record*. Total depth of well, 120 ft.; diameter, 8 in.; depth to foot-piece, 106 ft.; foot-piece to umbrella, 115.5 ft.; water eduction pipe, 5 in.; air pipe, 1 1/4 in. The lift developed an efficiency of 59.6 per cent measured between the steam end of the compressor and the point of delivery of the water. Air consumption was 50 cu. ft. free air per minute. The curve of efficiency shows a steady falling off as the pressure is increased and more water pumped. Thus with 100 cu. ft. free air per minute, pumping 392 gal. per minute, the efficiency was only 40.2 per cent. This decrease is expected for two reasons: First, because of the lower submergence when pumping the larger quantity; second, because of the greatly increased friction of water and consequently slippage of air at the higher velocities of discharge. This friction and slip is held to be the greatest contributing cause of inefficiency in air-lifts.

Power and Transportation

Diesel Engines vs. Steam Turbines for Mine Power Plants.—In a paper to be presented at the Arizona meeting of the American Institute of Mining Engineers, Mr. HERBERT HAAS of San Francisco discusses the subject of cheap power for mining and metallurgical plants, and gives some comparative data on Diesel engines and steam turbines. The supply of cold water for condensing purposes is a factor of importance, since about twelve times as much water will be required for condensing purposes with steam turbines under general conditions as is needed for jacket-cooling of two-stroke cycle Diesel engine; four-stroke cycle Diesel engines require only one-twentieth of the cooling water. Another condition favoring the use of Diesel engines is the high load factor at which most mine power plants operate.

The author tabulates the cost of producing power with (a) four 3000 B.h.p. (2000 kw.) Sulzer Diesel engines direct-connected to alternators and exciters, and (b) with two 6000-kw. steam turbines. For a plant of each type costing \$720,000 and fixing usual costs for labor, maintenance (1 per cent cost of installation per year), interest and amortization, and fuel oil at \$1.25 per barrel of 320 lb., the following comparative cost data are deduced:

	8000 Kw.		6000 Kw.		4000 Kw.		2000 Kw.	
	Per Kw.-yr. Doll.	Per Kw.-hr. Cts.	Per Kw.-yr. Doll.	Per Kw.-hr. Cts.	Per Kw.-yr. Doll.	Per Kw.-hr. Cts.	Per Kw.-yr. Doll.	Per Kw.-hr. Cts.
Diesel engine	39.81	0.4515	44.51	0.5081	53.89	0.6152	83.96	0.9256
Steam turbine	61.75	0.7051	63.50	0.7230	76.60	0.8746	111.70	1.2778

In general, the selection of either type of prime mover will be governed by the following economic considerations:

1. Fuel is of chief influence on the total power cost where both the B.t.u. price and load factor are high. These conditions favor the use of the Diesel engine.

2. Interest and redemption (amortization) are of chief influence on the total power cost with low B.t.u. price and low load factor; this applies particularly to stand-by plants, which are operated only occasionally or have to supply recurring peak loads. The installation cost of such plants must be kept as low as possible so as to avoid heavy capital charges distributable over a relatively small kilowatt-hours output of the station. Such conditions favor the steam turbine.

3. Exceptions to (2) are cases where the constant and instant readiness of the Diesel engine give it preference, and installation cost is of secondary importance. Here we would have to balance the cost of keeping boilers under steam continuously against the difference of interest charges of steam-turbine and Diesel engine plants.

4. Power plants located at the source of the fuel, either in the oil fields, or at the coal mine, and therefore enjoying the advantages of a very cheap fuel supply, will select prime movers costing least to install, i.e., steam turbines, since fuel expenditures will weigh less than interest and redemption charges.

5. In many cases combination plants using Diesel engines for supplying the continuous and nearly constant main load, and steam turbines for furnishing periodically occurring peaks by the use of high-duty boilers with large water and steam spaces, capable of being forced when necessary, will prove most profitable. Thus, as an example, the periodical peaks produced in hoisting may be taken care of by a turbine floating on the line and operating in parallel with Diesel engines that supply the main load and operate constantly at or near full load.

6. Steam power will remain the cheapest power wherever waste-heat gases are available, as for instance gases from reverberatory smelting furnaces, where nearly one-half of the fuel used in smelting can be utilized for steam generation. Nearly 3,000,000 B.t.u. for every ton of charge smelted are thus available for steam generation, or about 150 hp.-hr. per ton of charge which is smelted.

7. Up to capacities of 1000-hp. steam turbines can compete with Diesel engines only in special cases, such as supplying exhaust steam for heating purposes. For such small units, particularly for greatly varying loads, high-grade reciprocating steam engines are preferable. For larger plants, from 1000 to 10,000 kw. capacity, careful analysis must be made of the relative advantages of Diesel engines and turbines, a knowledge of the load factor, fuel prices and water conditions being necessary. Power plants larger than 10,000 kw. using units from 6000 kw. upward, preferably use steam turbines, unless a combination of high load factor, high fuel cost, and poor water conditions favor a Diesel plant. This is a special condition frequently met with in actual practice.

Recent Chemical and Metallurgical Patents

Iron and Steel

Opening Frozen Tap-Holes.—A method of opening frozen tap-holes of blast or open-hearth furnaces, patented by HENRY C. WITZ, of Johnstown, Pa., consists in applying a heated iron bar to the hard or frozen metal in the tap and continuously feeding oxygen to the heated bar so as to maintain the latter in an incandescent condition and thus enable it to eat its way through the frozen crust. (1,186,358, June 6, 1916.)

Treatment of Ores to Produce Alloys.—The direct production of an alloy of iron and nickel, or iron and any other metal such as manganese which may be contained in iron ores, is patented by FREDERICK A. EUSTIS, of Milton, Mass., and CHARLES P. PERIN of New York City, and assigned to the Moa Bay Iron Co. The object is to avoid the separate extraction of one of the contained metals when it is possible to obtain a desirable alloy by direct reduction. Considering the case of Cuban iron ore containing about 1 per cent of nickel, a parcel of ore is divided into two parts, one of which is to be treated for the extraction of a predetermined amount of its nickel which is subsequently added to the second part, thereby enriching the mixture in nickel, whereupon the mixture is smelted to produce an iron-nickel alloy. The treatment of the first part of the ore for extraction of nickel may be accomplished by roasting with sulphur-bearing material, yielding a sulphated product from which nickel sulphate can be leached. The nickel solution thus obtained may be precipitated, and the precipitate added to the second part of the ore prior to smelting. Various modifications of the method are given. (1,185,187, May 30, 1916.)

Copper, Lead and Zinc

Process of Refining Copper.—A substitute for the ordinary method of refining copper by oxidizing and then reducing with poles is patented by EDWARD C. KING, of Cananea, Mex. His method consists essentially in introducing hydrocarbon oil under suitable pressure into a bath of molten copper. He claims that the oil not only acts to eliminate gaseous or metallic impurities, forming a slag of the latter, but after all the impurities except oxygen have been removed, continuation of the operation will ultimately expel oxygen and give a refined copper. (1,183,736, May 16, 1916.)

Hydrometallurgy of Lead and Zinc Ores.—A method of treating lead and zinc sulphide ores by roasting and leaching with a chloride solution is patented by ROYAL S. HANDY, of the Bunker Hill & Sullivan Company, Kellogg, Idaho. The roast is conducted so as to yield as much lead sulphate as possible, after which the material is agitated with hot sodium chloride solution. Lead goes into solution as chloride, and when the solution cools much of the lead salt crystallizes out, while the solution can be used again or diverted to a regenerating system. Any unconverted sulphides remaining in the roasted material may be recovered by leaching with ferric chloride, whereby chlorides of the metals are obtained and precipitated on suitable metals: lead on iron, silver on lead, etc. The zinc solution may be electrolyzed. (1,185,902, June 6, 1916.)

Dry Chloridizing of Sulphide Ores.—In a patent issued to JOHN L. MALM, of Denver, Colo., the inventor discloses his method of treating sulphide ores of lead, zinc and iron, with dry chlorine gas, rendering the iron insoluble and the other metals soluble. The essential apparatus includes a tube-mill, a roasting furnace and an agitating machine. The dry ore is introduced into the tube-mill where it is subjected to the action of dry chlorine gas. Reaction proceeds to a point of par-

tial chloridization of the valuable metals and the formation of either ferrous or ferric chloride. The partly chloridized mass is then passed to the roasting furnace where chloridization is completed by the decomposition of the iron chloride, forming inert iron and manganese compounds and yielding chlorine to complete the chloridizing of the other metals. The latter are thus rendered soluble, and separation from iron and manganese offers no difficulty. Any gold and silver in the ore may be recovered by cyanidation or amalgamation after the pulp is agitated with the leaching solution and filtered. The leaching solution is hot water, which takes up the chlorides of lead, copper and zinc, leaving the inert iron and manganese compounds behind. (1,185,817, June 6, 1916.)

Electrolytic Apparatus.—An electrolytic cell in which the anodes are placed vertically above the cathodes is shown in Fig. 1, being the patented invention of WILLIAM E. GREENAWALT, of Denver, Colo. Another feature of the cell is the anode bell which collects the anode gases, either chlorine or oxygen, depending on whether copper chloride or sulphate is electrolyzed. The oxygen thus formed may be removed for the treatment

bleaching powder is added to effect oxidation of iron and manganese. These metals separate in gelatinous form, but small amounts remain in colloidal form, difficult of separation. These are then removed by boiling with hydrated silicic acid, formed by neutralizing sodium silicate with a mineral acid. When the neutralization is effected and the solution heated, insoluble silica is precipitated and carries down with it the remaining traces of iron and manganese. From the pure zinc sulphate solution thus prepared, zinc oxide or metal can be formed by appropriate means. (1,185,757, June 6, 1916.)

Treatment of Flue-Dust.—In Fig. 2 is given a diagram of a method of treating flue-dust from roasting or blast furnaces, according to the specifications of a patent granted to FRANCIS C. RYAN, of Hammond, Ind. The material is first leached with hot water to extract

all water-soluble compounds, such as the sulphates of zinc, arsenic and iron. The leach liquor is blown with air to oxidize the iron in particular. The residue is sulphated by roasting with sulphuric acid, the excess of which aids in the solution of basic anhydrous salts of iron, copper, zinc, etc. The roasted material is boiled with a limited amount of water, and the sulphate solution of silver, copper, zinc and iron is separated by filtration. To it is added the water solution first obtained, and the whole is precipitated with zinc oxide, throwing down iron, bismuth, arsenic, antimony, selenium and tellurium, while the sulphates of silver, copper, zinc and cadmium remain in solution. Precipitate and solution are separated, and treated for the recovery of their metallic contents by acceptable metallurgical methods. 1,182,320, May 9, 1916.)

FIG. 2—TREATMENT OF FLUE DUST

of ore by cyanidation, in which process oxidation plays an important part. Since the oxygen obtained from electrolysis at high current densities contains much ozone, the gas has an enhanced oxidizing power. Referring to the figure, 1 represents a shallow tank mounted on wheels; 4 is an inverted tank or anode bell suspended by suitable means as shown and dipping below the electrolyte in the cell. The cathodes are represented at 6 and the anodes at 7. Connections for anodes and cathodes are shown at 9 and 10, and inlet and outlet for solution at 11 and 12. Since the anodes are placed vertically over the cathodes, the anode gases will rise through the electrolyte into the anode bell and will not come in contact with the deposited metal at the cathode. The rising of the anode gases and the prevention of short-circuiting is facilitated by the oscillation of the anode bell, which has a small amplitude of vibration. (1,183,188, May 16, 1916.)

Hydrometallurgy of Zinc Ores.—A method of preparing pure zinc sulphate solution from zinc ores, particularly from roasted silicate zinc ores, is patented by SHUNJIRO ARAKI, of Osaka, Japan. The pulverized roasted ore is treated with the chemical equivalent of a 20 per cent sodium bisulphate solution, dissolving the zinc, together with lead, copper and small quantities of iron and manganese. The solution is filtered and treated with zinc in the form of dust or sheets to remove the copper and lead. The solution is next neutralized with caustic alkali, and an oxidizing agent like

bleaching powder is added to effect oxidation of iron and manganese. These metals separate in gelatinous form, but small amounts remain in colloidal form, difficult of separation. These are then removed by boiling with hydrated silicic acid, formed by neutralizing sodium silicate with a mineral acid. When the neutralization is effected and the solution heated, insoluble silica is precipitated and carries down with it the remaining traces of iron and manganese. From the pure zinc sulphate solution thus prepared, zinc oxide or metal can be formed by appropriate means. (1,185,757, June 6, 1916.)

Treatment of Flue-Dust.—In Fig. 2 is given a diagram of a method of treating flue-dust from roasting or blast furnaces, according to the specifications of a patent granted to FRANCIS C. RYAN, of Hammond, Ind. The material is first leached with hot water to extract

New Development in Castings of a Heat-Resisting and Non-Corroding Alloy

It is well known that there are very few metals or alloys which are suitable for working at temperatures between 1750 to 1800 deg. Fahr., without losing their strength rapidly, being volatilized or melting completely, and at the present time there is nothing in this line generally commercially available for industrial purposes.

The Driver-Harris Wire Co., Harrison, N. J., manufacturers of the nickel-chromium alloy "nichrome," which is well known in the electrical trades throughout the world as a resistor, has been, for some time past, developing this product in the form of castings and this research has been quite successful and remarkably interesting results have been achieved; the most important of which is, no doubt, the demonstration and practical service with extreme long life of "nichrome" in the cast form, compared with iron for work at high temperatures.

The company has been manufacturing these castings now for about a year and they are used in a great variety of different lines of industrial work. Patents have been assigned to the company by Mr. John C. Henderson, an engineer of the company, for the manufacture of these castings.

One of the new cast products of "nichrome," which has found much favor among manufacturers, especially in the automobile industry, is the carburizing box, used for heat-treating many different kinds of steel parts.

HEAT-TREATING BOXES OF NICHROME

Among the advantages which we note casually in this product, over the cast-iron box, are the following:

It possesses the characteristics of retaining its strength, as well as its shape, at high temperatures and does not become distorted, warp or bulge, as in the case of the iron boxes.

Marked economy is noted through saving in time, as the "nichrome" box may be quenched in water while red hot, thus saving the space and handling of reserved iron boxes.

Due to its far greater durability it may be made one-half the thickness of the iron box and thus save considerable labor in handling. These boxes may be had with walls cast $\frac{5}{16}$ in. to $\frac{1}{2}$ in.

Due to the fact that the box retains its strength and does not bulge the capacity of the furnace and tonnage of the product treated are increased appreciably. In the case of iron boxes it is a common thing to see the box cave in or warp badly. Another important advantage which should not be overlooked on this cast box, is the economy through long life, as the box loses very little of its tensile strength at working temperature of 1750 to 1800 deg. Fahr.

Among the cast products of the alloy, we find the much used pyrometer protection tube. This type of tube is now used very extensively and it is rapidly displacing the porcelain tube, which is fragile and very easily broken. In one case the tubes showed a life of 4000 hours.

It may be well to mention that a very interesting line of research is being conducted on metal crucibles of nichrome. Indications now are that these crucibles will very materially change the present practice in the melting of copper, brass and similar materials. Some very interesting results have been obtained from crucibles made to hold up to 175 lb. of metal and various metals have been melted to observe the effect which they had on the crucible. Brass, copper and phosphor copper have been melted, without the crucible showing any signs of deterioration. This is very important when we consider that phosphor copper has a corroding action on most all types of crucibles.

The writer saw one nichrome crucible in which phosphor-copper had been melted and which had been placed in white-hot coke and which had been used in oil vapors and other kinds of fire. About 50 heats had been made in this crucible and no signs of deterioration were visible. The nichrome crucible possesses the desirable property of not "alloying."

Tests made in No. 40 to No. 50 crucibles (the crucibles hold about 3 lb. to a number, thus No. 50 holds about 150 lb.), showed that metals could be melted quickly. Melts were made in about 40 minutes and required no especially careful handling or preliminary seasoning. The tests on the crucibles have not been entirely completed and it will be some time before the company will place them generally on the market.

Among other interesting products which have been made is a skimming ladle to be used in connection with a brass pot. When the brass pot is poured, the ladle is held in the neck of the pot, to keep back any dross or foreign substance floating on the top. Furnace bottoms, supporting frames, furnace floors to cover the fire bricks in heat-treating furnaces and in the chains and conveying parts of the continuous furnaces are other interesting uses. Furnace nozzles for oil burning have been tried out successfully, glass molds are being experimented with and a large pot for lead hardening and cyanide hardening has also been tested and has been found to offer many advantages. Some sections of pipe 15 in. in diameter and about 12 in. long have also been made.

It might be well to mention some of the other properties of nichrome as they should prove of general interest. In using nichrome wire baskets for pickling purposes and for heat-treating work, one of these baskets was used for six months in acid-dipping in which it was subjected to 40 deg. nitric acid, 40 deg. muriatic acid and 66 deg. oil of vitriol, also a mixture of several acids. No signs of the metal being affected were apparent. An ordinary brass basket lasted only four to six weeks at the same sort of work. In another case, a basket for heat-treating work was run through an annealing furnace at 1400 deg. Fahr. and dipped hot in 1:4 sulphuric acid. This process was carried on 140 times without any effect on the basket.

Nichrome can be readily machined, requiring no special tools. It has a tensile strength about twice that of ordinary cast iron and about the same hardness.

The development of these heat-resisting castings is very interesting and while some products are fully developed, the industry is just getting started and interesting developments in the future may be looked for.

The company expects to carry on considerable research work in the development of new castings.

Uranium in High-Speed Steel

The most recent development in high-speed steel is the remarkable effect of the alloy uranium on this class of material. This is shown by the results of tests of uranium high-speed steel in comparison with regular high-speed steel at present in use, given in Table I.

TABLE I

Tool	Feed, In.	Speed, F.p.m.	Cut, In.	Remarks
U-a	3/32	103	3/8	Ran 5 in.
A	3/32	103	3/8	Ran 2 1/2 in.
Material cut: loco axle				
U-a	1/16	74	5/8	Ran 12 in.
A	1/16	74	5/8	Ran 2 in.
U-a	1/16	94	5/8	Ran 5 in.
A	1/16	94	5/8	Ran 2 in.
Material cut: loco crankpin				
U-1	1/16	75	1/4	Went over once distance of 14 in. (in second lap went 3 in.)
B	1/16	75	1/4	Went distance of 4 in.
D	1/16	75	1/4	Went distance of 1 in.
Material cut: 50 per cent carbon 12 in. shaft				
U-1	1/16	51	5/8	Went over twice. Cut changed to 3/8 in. on second turn.
C	1/16	35	5/8	Did not go 1 in.
Material cut: 8 in. shaft 7 ft. 5 in. long				
U-1	1/32	75	5/8	Ran 18 in.
U-2	1/32	75	5/8	Ran 13 in. Speed increased to 90 f.p.m. and ran 11 in. Tool still good.
B	1/32	75	5/8	Ran 11 in.
Material cut: 6 in. shaft				
U-4	1/16	60 to 65	5/8	Went 8 in.
U-2	1/16	65	5/8	Went 4 in. Speed increased to 80 f.p.m. and went 3 1/2 in.
Material cut: 10 in. shaft				
U-1	3/64	55	5/16	Went 16 in.
U-5	3/64	55	5/16	Went 15 in.
B	3/64	55	5/16	Went 2 1/2 in.
Material cut: 12 in. shaft 22 ft. long				
U-5	1/16	45	5/8 to 3/4	Ran 57 in. Most of time the nose of tool was right on scale.
U-5	1/16 to 1/10	38	15/16	Went 127 in. Time 3 hrs. Speed increased to 65 f.p.m. after 105 in.
U-5	1/16	60	1 1/16	Ran 12 in.
Material cut: 12 in. forging				

The tools marked A, B, C and D are regular high-speed steel tools. Those marked U are uranium high-speed steel tools.

The manufacture of uranium high-speed steel is being taken up by a number of concerns. The tests of Table I were made under the direction of the Standard Chemical Company on a commercial scale at a number of the important shops in the Pittsburgh district.

Second National Exposition of Chemical Industries

The managers of the Second National Exposition of Chemical Industries which will be held at the Grand Central Palace, New York, during week of September 25-30, 1916, report that all space on the main floor has now been engaged, and that they have had to arrange for the second floor on which a great deal of space is already taken by exhibitors.

It is on this floor that the Government is expected to exhibit. Here also the "Made-in-America" meetings of the American Electrochemical Society will be held in the conference auditorium which the managers are erecting. The industrial conferences of the American Chemical Society, which will be presided over by its officers, in which heads of industries will participate, will also be held in this conference hall.

The American Paper and Pulp Association have their program in progress, and the managers report that they are organizing a section for the paper and pulp industry, which will cover considerable space on the second floor showing paper-making machinery, materials, products and by-products.

All motion pictures, covering every phase of industry, will be shown on this floor during the Exposition.

Several other societies have signified their intention

of supporting and exhibiting at the Exposition but have not as yet made known their programs.

With all these things, it is an assured fact that this exposition will transcend all the bounds of success of the former held last September.

Personal

Mr. Glenn L. Allen is now metallurgist for the Shattuck-Arizona Copper Company, Bisbee, Ariz.

Mr. M. H. Atwater is in charge of the erection of the electrolytic zinc plant for the Judge Mining & Smelting Company at Park City, Utah.

Messrs. C. C. Brayton and E. R. Richards have opened offices in the Hobart Building, San Francisco, as mining and metallurgical engineers.

Mr. H. Kenyon Burch, chief engineer for the Inspiration Copper Company, is taking a vacation in the East, following the completion of work on the design and construction of the company's concentrating plant in Arizona.

Mr. George A. Guess, professor of metallurgy in the University of Toronto, has been retained to start the copper smelter of the Vermont Copper Company at South Strafford, Vt.

Dr. Henry M. Howe, emeritus professor of metallurgy in Columbia University, has been appointed honorary vice-president of the Iron and Steel Institute of Great Britain.

Mr. E. C. Irwin has been appointed Cincinnati, Ohio, representative of the Asbestos Protected Metal Company, Pittsburgh.

Mr. Robert M. Keeney has resigned his position with the Snyder Electric Furnace Co. and is at his home in Chicago.

Mr. R. L. Lee has been appointed superintendent of the smelter of the Central Chili Copper Company at Panulcillo, Chile.

Mr. J. H. O'Brien of the American Blower Company, has been transferred from the Detroit office to the Chicago office, where he will give special attention to the air conditioning field in that territory.

Mr. H. A. Plusch, for the past seven years chief ceramic chemist for the Atlantic Terra Cotta Company, has resigned to take up the general field of consulting engineer in firebrick, refractory slab, terra cotta, faience, saggar, stoneware, sanitary ware, development of clay lands and new clay products. His offices will be at Perth Amboy, N. J.

Mr. W. H. Staver, formerly manager for the Liberty Bell Gold Mining Company, Telluride, Col., is investigating manganese deposits in the Southeast, and has opened an office in the Krise Building, Lynchburg, Va.

Messrs. Maurice W. Summerhayes and C. H. Poirier, respectively managers for the Porcupine Crown and Porcupine Vipond companies, have been selected to value the McIntyre, McIntyre Extension and Jupiter properties to determine the basis of a merger.

Dr. F. W. Traphagen, Golden, Col., has accepted the presidency of the Colorado Metal Mining & Reduction Company, and will devote his time to the company's metallurgical interests.

Mr. Charles E. van Barneveld is in New York on professional business and may be addressed care of the American Institute of Mining Engineers.

Mr. William H. Warren has been appointed manager of the works of the Brier Hill Steel Company at Youngstown, Ohio.

Mr. George J. Young, professor of metallurgy in the Colorado School of Mines, recently visited metallurgical plants in Nevada and California. He is spending the month of July on an outing in California.

Obituary

Sir William Ramsay, the eminent English chemist, died at his home, Beechcroft, at Haglemere, Bucks, in his sixty-fifth year, on July 23. He was born in Glasgow and educated in Glasgow Academy and University. He then took up teaching work and was subsequently associated with a number of universities, the last one being the University College of London, from which he retired as professor emeritus of chemistry in 1913. He was perhaps best known for his work on the gases of the atmospheric, including the discovery of argon in collaboration with Lord Rayleigh. He was the author of many valuable contributions to chemical literature, chiefly on the gases of the atmosphere, production of helium from radium, and general physical chemistry. He visited this country several times and was Lovering lecturer at John Hopkins University. He also delivered a number of lectures at other institutions. He was the recipient of the Nobel prize in 1904 and received a number of other prizes for his work. He was president of the Seventh International Congress of Applied Chemistry in London in 1909; was a past president of the Society of Chemical Industry and Chemical Society, and was a member of a large number of scientific societies.

Charles W. H. Kirchhoff, editor of the *Iron Age* from 1889 until 1910, and a past president of the American Institute of Mining Engineers, died at his summer home, at Asbury Park, on July 23, in his sixty-fourth year. He was born in San Francisco, Cal., and was graduated from the Royal School of Mines in Clausthal, Germany, in 1874. He returned to this country and was chemist of the Delaware Lead Refinery, Philadelphia, Pa., for three years. He joined the *Iron Age* in 1878 and remained until 1881, when he became managing editor of the *Engineering and Mining Journal*, returning to the *Iron Age* in 1884. In January, 1910, he was tendered a luncheon at the Engineers Club in New York by a number of his friends, in recognition of their admiration for him as an editor and a man. This was on the occasion of his retirement as editor of the *Iron Age*, with which he had been associated for over 30 years. He was a member of the American Iron and Steel Institute, The Iron and Steel Institute of Great Britain, The American Society of Mechanical Engineers, The Verein Deutscher Eisenhüttenleute and an honorary member of The Franklin Institute of Philadelphia.

Samuel Waterhouse, Jr., organic chemist, for some time past superintendent of the Frank L. May Chemical Company of Perth Amboy, N. J., died in the City Hospital of that city of aniline poisoning on July 8.

Industrial Notes

Nickel Refining—Premier Hearst, chairman of the Provincial Government Nickel Commission of Canada, is experimenting with an electrolytic nickel refining process, and considerable money will be spent on equipment.

The plant of the Virginia-Carolina Chemical Co., at Americus, Ga., was struck by lightning on July 10, and was subsequently destroyed by fire. The plant is said to be insured.

New Porcelain Ware Made in United States—The Guernsey Earthenware Co., Cambridge, Ohio, have issued Catalog No. 5 describing its new product, "Guernsyware," chemical laboratory porcelain. Tests made on

this porcelain have shown it to be the equal of the imported ware, and satisfaction is expressed by those who have used the products.

The German American Car Company announces a change in name to the General American Tank Car Corporation, and will continue its business under the same management and in the same manner as in the past, but with largely increased facilities.

The Block Chemical Laboratories of Chicago were incorporated under the laws of Illinois on June 16. The officers are: Dr. D. Julian Block, president; Prof. Robert M. Cole, vice-president, and Howel B. Keeler, secretary.

The Kansas Chemical Mfg. Co., at Hutchinson, Kan., is constructing a new \$30,000 hydrating plant and a \$20,000 lime plant of four kilns at Moline, Kan., where limestone quarries are located. The new plant will be ready for operation in about two months.

The Providence Engineering Society will occupy its new rooms at 29 Waterman Street, Providence, R. I., when it opens up for its fall and winter work next September. The whole second floor of the building has been taken over and will be remodeled and equipped in a modern and attractive manner. The society expects to pursue a very interesting and useful line of work for the coming year.

The Commercial Attache of the American Embassy at Paris, France, Mr. C. W. A. Veditz, is desirous of receiving catalogs, price lists and similar printed material from American concerns interested in the French and Spanish markets. The commercial office is in receipt of numerous inquiries for the names and addresses of American firms producing a variety of products and desires to have the catalogs on hand to show to inquirers.

The Hoskins Manufacturing Company, Detroit, Mich., announces a change in the address of its Boston office from 613 Unity Building, to 445 Tremont Building, 73 Tremont Street. The office will continue to be in charge of Mr. J. E. Hines.

Pulverized Coal in Open-Hearth Furnaces.—The Raymond Bros. Impact Pulverizer Co., Chicago, Ill., has recently received an order from the Carnegie Steel Co. for seventeen of its largest sized mills for pulverizing coal for use in open-hearth furnaces. Other orders have recently been received for experimental and complete installations.

New Building for Manufacture of Rubber Gloves—The Lee Tire & Rubber Co. has just placed with John W. Ferguson Co. of New York, and Paterson, N. J., a contract for the erection of another building at its Conshohocken plant. To this building will be transferred that portion of the company's business which has to do with the manufacture of rubber gloves and similar rubber products. The building measures 80 ft. by 120 ft. in plan, and will for the present contain but two stories. The foundation and reinforced concrete columns on the first floor are designed, however, for several additional stories with the idea of probable expansion in view. A wooden roof will be placed over the second story. The walls of the building will be brick and the floors reinforced concrete. Steel sash will be used in the windows. H. M. Haven & Wm. W. Crosby of Boston drew up the plans and specifications.

The International Oxygen Company, with offices at 115 Broadway, New York, is installing a new plant at College Point, L. I., for the manufacture of oxygen and hydrogen gas. It is expected that the installation will be completed late in August or early in September after which the company's increasing trade in Brooklyn

and environs, as well as in Manhattan, will be largely handled from this point. Heretofore this local business has been supplied from the company's Newark works, and the new location will mean larger and better facilities and more prompt service in the supply of gases in cylinders. The manufacture of gas-generating apparatus is the main business of the company, this feature of its work being concentrated at the Newark factory. The manufacture and distribution of gas in cylinders is a local and a secondary feature. The Newark and College Point plants supply Greater New York and the adjoining industrial section of New Jersey. The plant at Verona, Pa., has its outlet in the Pittsburgh district.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath, Cathodes Metalizing

29,144, July 17, 1860, Joseph Corduan of Brooklyn, N. Y.

Relates to electroplating the face of type with brass. To a saturated solution of blue vitriol add a caustic potash solution until no further precipitate forms. The precipitate is "black oxid of copper." It is washed well, and dried. The dried oxid is added to a cold solution of potassium cyanid until no more dissolves. To a similar solution of potassium cyanid, heated to boiling, is added oxid of zinc until no more dissolves. Equal volumes of the clear solutions are mixed and used as the electrolyte, while for a hard brass, an excess of the zinc solution is used; and for a soft brass, an excess of the copper solution is used. Brass vats are preferred to hold the electrolyte, and the vat may serve as anode, or a separate anode may be inserted in the solution. The type are assembled and held in a brass clamp, the faces being perfectly level, and the faces only immersed in the electrolyte.

63,512, April 2, 1867, Samuel Hallock of New York, N. Y.

Relates to an apparatus used in electrotyping, and consists of a frame to support the wax mold, and an auxiliary frame carrying a plurality of light spring contacts to make electric contact with the graphite on the face of the impressed mold. All submerged metal parts are protected by a coating of wax or rubber, except the contacting surfaces of the springs.

83,747, Nov. 3, 1868, Dennis C. Wilcox of Meriden, assignor to Meriden Britannia Company, of West Meriden, Conn.

Relates to the manufacture of double-walled ice pitchers, and similar vessels, and consists in electroplating the unprotected surfaces of the enameled or glazed metal at the edges where they are to be joined, and then soldering the joint at the electroplated parts.

90,892, June 1, 1869, Hiram Tucker of Newton, Mass.

Relates to surfacing articles of cast metal which have raised and depressed portions. The depressed portions are filled with wax or other filling, and the raised portions, after suitably grinding and polishing, are electroplated with any desired metal. Or the raised surfaces may be electroplated first, and the depressed portions filled in with wax or the like, later.

94,453, Aug. 31, 1869, William T. Tibbals and Lyman B. Tibbals of Cohat, Conn.

Relates to electroplating the joined and riveted edges

of such articles as cow-bells, the electroplated joint constituting an electro-soldered joint, and is effected at the same time that the bell is electroplated.

102,077, April 19, 1870, Joseph A. Adams of Brooklyn, N. Y.

Relates to electrotyping, and consists of a holder constructed to receive the black-leaded type-mold and frame, and make contact with the frame only. The holder consists of a hinged clamp, which may be screwed tight against the frame, and is provided with two points or lugs which engage corresponding holes or recesses in the frame. At the lower end of the clamp extending behind the frame is an adjustable clamp to hold the lower portion of the frame.

114,447, May 2, 1871, Silas P. Knight of Brooklyn, N. Y.

Relates to coating an electrotype mold with graphite, the graphite being first moistened with alcohol, and then mixed in the proportion of 1 lb. of graphite with 1 gal. of water. The mold filled with wax is first coated with water and graphite, the impression of the type made, then the mixture of water and graphite applied in fine streams from a "rose," and the excess of graphite finally washed and brushed off. Instead of graphite, bronze or similar powder may be used.

168,442, Oct. 5, 1875, William E. Worthen and Richard S. Gillespie of New York, N. Y.

Relates to electroplating such metallic objects made of iron and zinc with copper. The object is first coated with a mixture of red mercury oxid, alone or mixed with some mercury sulfid, and a waterproof vehicle, such as oil, to form an oxid of mercury paint, and this coating is then covered with a film of graphite. The article is then immersed in a solution of copper sulfate, and electrodeposited as usual. It is thought the mercury oxid and sulfid are reduced to metallic mercury, thereby forming a good connection through the paint to the metal beneath. If desired, copper rivets or wires may be secured in the metal object, extending through the paint and graphite coatings, and be united to the electrodeposit. Instead of depositing upon a metal object, the deposit may be made upon an article made from a mixture of ground coke and asphalt, thoroughly mixed while hot and molded into the desired shape. Such articles are first coated with graphite in the recessed parts, and electroplated, then the remainder coated with graphite, and electroplated. With large objects, such as a fountain, it is put into a tank and the electrolyte gradually increased in depth until it is entirely immersed, the anodes being raised with the electrolyte.

199,366, Jan. 22, 1878, Gustave Hubmann of New York, N. Y., assignor to Felix Marx of same place.

Relates to ornamenting marble and the like by electrodeposition. The marble is first cleaned, then coated with a light-sensitive emulsion of bichromate of potash and gelatine, then a suitable design made of varnished paper is secured to the emulsion, and the marble exposed to the light to render the exposed emulsion insoluble in water. The design is then removed, and the coating is then treated with alcohol to harden the emulsion not exposed to light. The marble is then placed in hot water to remove the non-exposed emulsion, after which the marble is washed and treated with acid to etch the uncovered portions. It is then washed with water and treated with benzine to remove the remaining coating, then the etched parts are varnished and coated with graphite, pieces of wire or rivets also being secured to the marble to anchor the deposit, and then immersed in an electrolyte to be copper-plated, after which the marble and deposit are polished and the metal engraved if desired.

Who Produces the Metals?

The national advantage of holding premier rank among the world's metal-producing countries has been accentuated by the war. To both belligerent and neutral nations the control of the output of any metal has become an important asset, either through supplying domestic needs or by increasing revenue through sales to neighbors less fortunately situated. The international scramble for metals has directed attention most forcibly to the sources of the world's metal supply and has brought into prominence some of those that hitherto have been obscure or relatively unimportant.

Among precious metals, 60 per cent of the world's production of gold is controlled by Great Britain, mainly in South Africa and Australasia. This, together with the further fact that less than 1 per cent of the world's gold comes from European countries, has undoubtedly had a great economic effect in the conduct of the world's business during the war. The United States holds second rank in the production of gold, but first in the case of silver, producing about 30 per cent of the world's total. Under normal conditions Mexico would be a close second, with Canada, Australasia and Germany following. Russia is unquestionably the leader in platinum, as no new source has appeared comparable with the placers of the Urals. Colombia is next in importance to Russia, but, besides these two countries, the others, including our own, make but nominal output.

In pig-iron and steel the United States easily holds first rank, with an average production in recent years of about 40 per cent of the total. Germany follows with about 25 per cent. The United Kingdom is third, and France and Russia divide fourth place.

The pre-eminence of the United States also becomes apparent when considering the common base metals—copper, lead and zinc. Of late years we have produced about 55 per cent of the world's output of copper. In 1913 the next nearest competitor, Japan, turned out only 7 per cent of the whole, which clearly demonstrates our own position. Chile, Australasia, Spain, Mexico, Germany and Canada follow with minor percentages. With regard to lead our position is not so strong, though we still lead other countries with a production of about one-third the total. Spain takes second place, with about one-fifth, with Germany and Australasia following. Mexico has held a stronger position than she now occupies, having produced more than one-tenth of the world's output during the period 1903-1911. In spelter production we were credited in the years 1909-1913 with slightly over 30 per cent of the whole. It is greater at the present time, due not only to increased production at home, but also to enforced curtailment abroad. Germany, which for years has distilled the

major portion of zinc concentrates from Australia, has been a very close second during this period, but has not quite equalled our output. Belgium was third with about 20 per cent, and the three countries together accounted for over 80 per cent of the world's spelter. France, Spain and Great Britain have been in minor positions.

Among the minor metals our position is not so prominent. In quicksilver production, Spain, Italy and Austria all surpass us in the order named, Spain producing more than twice as much as the United States. Since 1908 China has led in antimony, producing from two to three times as much as France, which holds second place. Practically all the antimony metal used in the United States is imported from European smelters, our own production being confined to that contained in antimonial lead. Our position is more favorable with regard to aluminium. Estimates of the world's output for 1914 credit the United States with almost half the total; France about one-seventh; Switzerland about one-eighth. Great Britain, Canada, Norway, Austria-Hungary and Italy provide the balance. In the case of nickel we again lead, through our refining of Canadian mattes, but not from treating domestic ores. New Caledonia is the only important competitor of the Sudbury district, Canada, in the production of nickel.

When it comes to the less common metals like molybdenum and tungsten, we realize the world's dependence on relatively obscure sources, though greater domestic production might be stimulated by unusual conditions. No commercial production of molybdenum was reported in the United States in 1914, and the world's principal supply came from Australia. Norway also was an important producer and Canada had made some production. During the past year both domestic and Canadian production has been stimulated. In tungsten we hold a more important place, being second to Burma, which took the lead in 1912. For the period 1912-1914 we produced about 14 per cent of the tungsten of the world, while Burma is credited with 18 per cent.

On the whole, the position of the United States is seen to be an important one. Of the thirteen metals considered, we hold first rank in the production of seven and second in the case of two. In the balance our output is of minor importance, if not negligible.

Congress and Technical Affairs

Consider the Congressman, how he votes. Occasionally it seems almost as though he knew not, neither did he think. And yet the engineer with all his knowledge is not clothed with the political power of one of these. All of which points a double moral: the necessity of the education of our law-makers in technical matters, which can be accomplished only through greater activity of engineers in the realm of public affairs. Too long has the engineering profession held aloof from those who make our laws and run our government, forgetting that much of the business of state is concerned with problems in organization, management and economics, for which successful engineers should be well fitted.

The fault, when such exists, lies not altogether with public servants, many of whom would lend a willing ear to sound advice on technical matters. Never was a time so propitious for such advice as the present, when public officials are called upon to legislate on matters affecting our industrial growth and welfare, the technique of which is best appreciated by scientists and engineers.

In our last issue, for example, we called attention to the intricacies of the several proposals for a protective dyestuff tariff, and showed that while progress has been made toward an intelligent consideration of this most important matter, it may yet fail of the full measure of attention it demands. And who so well qualified to point the way, avoid the pitfalls and prevent the passage of an abortive half-measure as those who know the technical phases of the industry?

Recently the subject of scientific management received consideration at the hands of Congress in such a manner as to elicit caustic criticism and ridicule from layman as well as engineer. The House passed a bill forbidding time and motion studies on government employees, and prohibiting the adoption of any scheme of remuneration involving bonuses or premiums for excellent work. This is a sad and disgusting spectacle, considering the truly remarkable achievements of scientific management and organization in various industrial lines. It is typical of the manner in which Congress plays politics with matters that should receive intelligent and broad-minded treatment. Instead of welcoming the possibility of placing the Government's business on a basis of efficiency, Congress yields to political pressure, throws a sop to a prejudiced faction, and holds departmental work to the dead level of mediocrity. At a time when private business is being forced to study efficiency and the whole country realizes the necessity of such action, and when one of the candidates for President is talking about "America Efficient," Congress exposes its own inefficiency by putting a spoke in the wheel of progress. Popular impression prevails that governmental departments are not on an efficient basis, and engineers can render a service to the country by expressing that opinion in a manner so forceful as to show Congress the light.

In matters more vital to the mining and metallurgical industries Congress acts with even less discretion. The recent proposed tax on copper for the purpose of raising revenue is a case in point, showing how illogically and superficially a profound subject may be approached. Apparently sensing a popular impression that copper is a highly profitable constituent of war munitions, and without first establishing a broad, fundamental, economic basis for raising revenue in an equitable manner, Congress singles out copper for taxation and gives itself over to class legislation of the wildest sort. If the storm of protest that has been aroused does not call the national legislature to its senses, it is indeed immune to criticism. Such unfair taxation as is proposed in the case of copper can be charged only to astounding ignorance of conditions. Admitting that taxation for revenue is a tremendous prob-

lem, there is the greater need to stop, look and listen before proceeding blindly.

We presume that instances might be multiplied to prove political inadequacy in dealing with technical affairs. Congressional proposals for the revision of the mining law, and political interference with the work of our technical bureaus furnish other examples. We need more representatives of science and industry in Congress, and fewer politicians and lawyers. Then, perhaps, the Government will conduct its business in a more efficient manner and without regard to political expediency. In the meantime, with all its unwise proposals in technical matters, Congress continues to caress the pork barrel with wonted satisfaction, unwilling to play its part in economy and efficiency. The situation calls for intelligent help, which it becomes the duty of engineers to offer.

The Bureau of Mines' New Stations

By an act of Congress passed over a year ago the Bureau of Mines was authorized to establish ten experiment stations for mining and metallurgy, in addition to the five already existing at Pittsburgh, Denver, Salt Lake City, San Francisco, and Urbana, Ill. It was provided that not more than three of the new stations should be established in any one year, and it was expected that their work would be supplemented by appropriations from the States in which they should be located. The first three of these stations are to be established this year, and the sum of \$25,000 is appropriated annually for each of them.

Two of the new stations have been definitely located at Fairbanks, Alaska, and Tucson, Arizona. The third will be placed somewhere in the Northwest, in Washington, Idaho or Montana, and Director Manning is now on a trip of inspection to decide the location. We understand that the selection will be made wholly with a view to the best service that can be rendered to the industry by the Bureau, and that political pressure or flattering offers of local assistance and cooperation will receive minor consideration. The station may go to Butte, Seattle, Moscow or Pullman, each of which is reported to be bidding actively for the director's favorable consideration.

The Arizona station will be at Tucson where the State school of mines is situated, and co-operative work will be carried on by the two organizations. Similar arrangements now exist at Salt Lake City, Urbana and Golden, where the Universities of Utah and Illinois and the Colorado School of Mines, respectively, have co-operative agreements. The station at Golden was recently removed there from Denver and is now occupying an entire building placed at its disposal by the Colorado School of Mines.

When it was first proposed to establish ten new stations, each with an annual appropriation of \$25,000, we opposed the plan because we believed a single station centrally located, with \$250,000 per annum at its disposal could do more effective work. It seemed, furthermore, that ten stations must inevitably duplicate equipment and staff to an alarming degree. Apparently it

was impossible to put such an economic measure through Congress, and Dr. Holmes, who was then director of the Bureau, made the best of the situation and accepted the ten stations as an alternative.

This plan is now going into effect and a definite line of work is being assigned to each station so that duplication of work, at least, is being avoided. Thus the Urbana station appropriately confines its work mainly to coal; Tucson will study problems relating to copper; Golden is devoted to investigations of the rare metals, and so on. The location of stations at State schools is a policy that should be fruitful of results for both parties to the arrangement. If the States make appropriations commensurate with the sums expended by the Bureau, double the amount of work can be accomplished at half the cost to either party. As a rule the schools are able to offer housing, equipment, laboratory and library facilities that save the Bureau a large sum of money and leave its funds available for research work.

In a measure the whole scheme of separate stations may be considered experimental, and the future policy of the Bureau probably will be determined by the success or failure of the plan. If, after a few years' trial, it is found inexpedient, the separate stations may be combined at a central point. In the meantime the whole industry, and particularly the States concerned, should make a consistent effort to support the Bureau in getting the best possible results.

Tungsten

According to statistics gathered by the U. S. Geological Survey, the tungsten production of the United States during the first six months of 1916 exceeded the production of this or any other country in any previous twelve months. The output was equivalent to about 3290 short tons of 60 per cent WO_3 concentrates, and was valued at \$9,113,000. If the tonnage was remarkable, the value was even more so. The last six months of the year probably will show a decrease in production and assuredly a marked reduction in value, for it seems certain that so spectacular a market for tungsten will not be experienced in many years, if ever.

Colorado has regained first place as a tungsten producer and Boulder is again the premier district. California is second, with Nevada and Arizona following. Nearly all of the western States reported some production. But if reports regarding a new tungsten discovery in Nevada are confirmed, Colorado and other States may be relegated to minor positions. A deposit remarkable both for its extent and grade of ore is now being developed and a concentrating mill is under construction. In addition to ore of milling grade, large quantities of shipping ore are reported.

The situation in Colorado has become more stable, and operators are wisely turning their attention to the production of such finished products as ferrotungsten, tungstic acid and metal, instead of marketing raw concentrates. Tungstic acid has been produced for some time by at least two concerns, and improved methods of treatment are reported as a result of the research that has been under way for the past year.

The Distribution of Silver Between Metallic Lead and Litharge—Containing Slags

To the Editor of Metallurgical & Chemical Engineering

SIR:—I have been much interested in the article by Prof. Boyd Dudley on "The Distribution of Silver Between Metallic Lead and Litharge-Containing Slags," which appeared in the issues of June 1 and 15. His research shows clearly among other things: (a) the advantage of using as little litharge-containing slag as consistent with good fusions; (b) the reason why a long, slow fusion of excess litharge slag, ending at a moderate temperature, gives a better silver result than a quick, hot fusion; (c) that the reduction of a small lead button in the crucible, resulting in a high silver concentration, will be accompanied by a high slag loss, which may, however, be partly balanced by a lower cupellation loss. These facts have in the past been more generally accepted than understood.

The question whether silver in assay slags is dissolved or oxidized is interesting, but difficult of proof one way or the other. The slags obtained in commercial copper matte smelting, to which Professor Dudley has referred, probably hold a part of their silver as oxide (*E. & M. J.*, Vol. 100, pages 215, 263, 305). If excess litharge flux be used for silver determinations, fairly good results may be obtained by performing the fusion in a strongly reducing atmosphere, which may be easily obtained by filling several crucibles with soft coal and placing them in the muffle with the fusions. This should not affect the solubility of silver in litharge, but might reduce silver oxide to some extent. Oxidation of silver is also suggested by the lower slag loss of gold, which is not readily oxidized. Probably oxidation and reduction both take place; if so, Professor Dudley's work shows that they obey similar laws.

Yours truly,

FRANK E. LATHE.

Rapid Analysis of White Bearing Metals for Copper and Lead

To the Editor of Metallurgical & Chemical Engineering

SIR:—The following method for the rapid analysis of white bearing metals for copper and lead has been used by me many times and I have found it very rapid and at least as accurate as any of the other technical methods for the determination of these two elements.

Take 1.0 g. sample in a 150 c.c. beaker, add a pinch of tartaric acid and 20 c.c. aqua regia, and heat to solution. Remove from the hot plate, rinse into 50 c.c. 25 per cent NaOH contained in a 400 c.c. beaker, add 15 c.c. 25 per cent Na₂S and heat just to boiling over the flame, keeping the beaker in constant motion. Remove from the flame, allow to settle a moment, and filter through an 11 c.m. hard paper (with suction). Wash four times with dilute hot Na₂S solution. Transfer the paper and ppt. to a 250 c.c. beaker, add 10 c.c. conc. HNO₃, boil until the paper is disintegrated. This should be carried on over a good flame. Now add 5 c.c. conc. H₂SO₄ and boil until the solution has turned black. Add 3 c.c. conc. HNO₃, and again boil until the solution turns dark. Repeat alternate additions of HNO₃ and boiling until the solution goes down to SO₂ fumes without any appreciable darkening. Remove from the flame, cool with the air

jet, dilute with cold aq. to 50 c.c. and if the percentage of lead is below ten, add an equal volume of grain alcohol. Stir well, allow to settle a moment and filter through an 11 cm. double paper. Determine the Cu either electrolytically or by iodometry. Determine the lead as sulphate, or by one of the standard volumetric methods. An analysis may be completed in one to one and a quarter hours.

Hoping this may be of service to your readers as it has been to me, I beg to remain,

W. L. JACKSON.

E. C. Atkins & Co.,
Indianapolis, Ind.

Western Water-powers and Electrochemical Industries

To the Editor of Metallurgical & Chemical Engineering

SIR:—Your comment in the issue of July 1, upon the article on the electrochemical possibilities of the Pacific Coast, by Mr. Beckman, in the same issue, furnishes incentive for discussion in the statement that "It would be plain foolishness to think that the abundant and cheap water-powers of the Pacific Coast could be made to supply the principal markets now supplied by the electrochemical industries of Niagara Falls . . . the manufacturing districts of the East and Middle West."

On second thought, is this statement entirely consistent with the statements of the advocates of Niagara Falls as against the rest of the country, that "large industries are being driven to Europe and to Canada on account of the famine of power which exists at Niagara Falls?"

Is it not a fact that the prices of electrochemical products and metals are based on seaboard deliveries, generally?

It will hardly be contended that there is any less tendency now than heretofore for the broad chemical and metal industries to seek the seaboard, around the world. It would, therefore, appear to be still true that the Atlantic, Gulf and Pacific seaboard are quite as important market and transportation factors as the Great Lakes.

Specifically, we would cite the case of aluminium, the most important electrochemical industry, and the one consuming the most power. It is hardly fair to contend that Niagara Falls and Canada is the natural and only feasible region for the economical production of aluminium; the ore going from Arkansas to East St. Louis for concentration, thence to Niagara Falls and Canada for reduction, and the metal again returning to St. Louis and to New York—the centers of population and manufactures of the Middle West and of the East, to which you refer—and wherein the ores and other considerable materials consumed in the production of aluminium, and the metal to market, are carried almost entirely by rail, at three to ten times the cost of water transportation.

The Great Lakes are certainly not a controlling factor in this electrochemical industry.

Wherein would really cheap water-power, and aluminium ores and carbonate of soda, and electrode carbon, within a few miles of seaports with cheap fuel, on the Pacific, be handicapped in comparison with Arkansas and Niagara Falls and Canada?

F. LANGFORD.

Eureka, California.

Metallurgical Plants of Arizona

A Brief Summary of the Extent of Metallurgical Practice in Arizona, and the Itinerary of the Tour of the American Institute of Mining Engineers

THE meeting of the American Institute of Mining Engineers in Arizona, Sept. 18 to 24 inclusive, directs attention to the important place which that State now occupies in mining and metallurgy. It holds first place in production of copper, having excelled Montana in that respect. It contains also within its borders, though not on the Institute route, the newest and most important gold-mining district, Oatman, where new metallurgical plants are in course of erection. In fact, general progress in mining, smelting, concentrating and cyaniding in Arizona has been so rapid and interesting that it holds unusual attraction for engineers who are fortunate enough to find time for even a brief visit to the principal districts. Technical skill is represented in the highest degree among the engineers who are in charge of operations, and they are not lacking in those qualities of friendliness and generosity toward the profession that make for progress through a courteous exchange of information. These features, combined with the fact that the Institute's president, Dr. L. D. Ricketts, has been a leading factor in the development of mining and metallurgy in Arizona, make the prospective meeting most opportune.

A special train will be at the disposal of the Institute party, leaving New York Thursday, Sept. 14, and arriving at El Paso, Tex., Sunday, Sept. 17. From El Paso the itinerary includes continuous visits for a week to the principal mining and metallurgical districts of Arizona, with a short stop in New Mexico, ending at the Grand Canyon on Sunday, Sept. 24. A brief outline of the tour follows; full details can be secured from Institute headquarters.

Monday, Sept. 18.—Mines of the Chino Copper Company and mill of Empire Zinc Company, Santa Rita, N. M. Mill of the Chino Copper Company, Hurley, N. M.

Tuesday, Sept. 19.—Reduction works of Copper Queen Consolidated Mining Company and of Calumet & Arizona Mining Company, Douglas, Ariz. Technical sessions on smelting and leaching.

Wednesday, Sept. 20.—Mines of the Bisbee district. Technical session on mining and geology.

Thursday, Sept. 21.—Mines and reduction works of Old Dominion Copper Company, Globe. Technical sessions on concentration, flotation and fine grinding.

Friday, Sept. 22.—Reduction works of International Smelting Company and mills of Inspiration Consolidated Copper Company and Miami Copper Company, Miami. Technical session on mining and smelting.

Side trips can be arranged from Globe to mines of the Ray Consolidated Copper Company at Ray, or over Apache trail to Roosevelt dam. The main party will travel via Phoenix to the Grand Canyon, where Sunday will be spent, after which the special train will return to New York.

The visits to mines and metallurgical plants, and the technical sessions will be interspersed with social functions, which will add pleasure and profit to the trip.

Summary of Metallurgical Plants

That those who plan to attend the meetings may have an idea of the extent of metallurgical practice in Arizona and a bird's-eye view of the processes and equipment that may be seen, not only on the Institute route but elsewhere in the State, we have prepared the accompanying map and data. The latter have been supplied mainly by officials of the different companies, or compiled from sources considered reliable. The order of their presentation is with reference to, first, the Institute main itinerary and scheduled side trips, and, second, other metallurgical centers in the State. Numerals and letters refer to locations on the map, the former indicating the Institute route and the latter other metallurgical centers.

Copper concentrating mills:
B Arizona Copper Company, Clifton.
F Consolidated Arizona Smelting Company, Humboldt.

B Detroit Copper Mining Company, Morenci.
3 Inspiration Consolidated Copper Company, Miami.
D Magma Copper Company, Superior.
3 Miami Copper Company, Miami.
3 Old Dominion Copper Mining & Smelting Company, Globe.

X Ray Consolidated Copper Company, Hayden.

B Shannon Copper Company, Clifton.

Copper reduction works:

C American Smelting & Refining Company, Hayden.
B Arizona Copper Company, Clifton.
1 Calumet & Arizona Mining Company, Douglas.
F Consolidated Arizona Smelting Company, Humboldt.

1 Copper Queen Consolidated Mining Company, Douglas.

B Detroit Copper Mining Company, Morenci.

3 International Smelting Company, Miami.

3 Old Dominion Copper Mining & Smelting Company, Globe.

B Shannon Copper Company, Clifton.

Z United Verde Copper Company, Clarksdale.

Cyanide mills:

A Commonwealth Mining & Milling Company, Pearce.

Z Copper Chief Mine (Hayden Development Company), Jerome.

G Gold Road Mines Company, Goldroad.

G Tom Reed Gold Mines Company, Oatman.

G United Eastern Mining Company, Oatman.

E Vulture Mines Company, Wickenburg.

On the Institute Route

1. Douglas. Calumet & Arizona Mining Co. smelting plant was completed in 1913, and contains two 48-in. by 40-ft. blast furnaces, four 19-ft. by 100-ft. reverberatory furnaces, twelve seven-hearth roasters 21-ft. 6-in. diameter, and six Great Falls type basic-lined converters. The plant is treating 3000 tons of charge per day and produces 7,000,000 lb. of copper per month. In addition to the smelting plant at Douglas, the company has under construction at Ajo a copper leaching plant which will have a capacity of 5000 tons per day. This plant is expected to be in operation early in 1917, and will be one of the most interesting examples of copper leaching in this country, producing 36,000,000 lb. of copper per year. Coarse crushing will be done with gyratories to about 3½ in., and with Symons disk crushers to ¼ in., at which size leaching will be done. Eleven lead-lined leaching vats will be 88 ft. square by 15 ft. deep, with an aggregate capacity of 5000 tons. Sulphur dioxide will be used for reduction of ferric iron

SKETCH MAP OF ARIZONA—LEGEND

The trip of the A. I. M. E. starts from El Paso, Texas, and the first stop is at Santa Rita and Hurley, N. M., to visit the mine and mill of the Chino Copper Co. From there the route lies through Arizona as shown below. Itinerary and points of metallurgical interest are indicated on the map by reference numbers and figures, as follows:

INTERESTS SHOWN IN ARIZONA

- 1 Douglas:
Calumet & Arizona Mining Co., Smelter.
Copper Queen Cons. Mining Co., Smelter.
- 2 Bisbee:
Copper Queen Cons. Mining Co., Mines.
- 3 Globe-Miami District:
International Smelting Co., Smelter.
Old Dominion Copper M. & S. Co., Smelter and concentrator.
Inspiration Cons. Copper Co., Concentrator.
Miami Copper Co., Concentrator.
- 4 Phoenix.
- 5 Grand Canyon.

SCHEDULED SIDE TRIPS

- X Ray:
Ray Cons. Copper Co., Mines.
- Y Roosevelt:
Reclamation project.
- Z Jerome-Clarkdale District:
United Verde Copper Co., Smelter.
Copper Chief Mine, Cyanide Mill.

OTHER METALLURGICAL CENTERS

- A Pearce:
Commonwealth M. & M. Co., Cyanide mill.
- B Clifton-Morenci-Metcalf District:
Arizona Copper Co., Smelter and concentrator.
Detroit Copper Mining Co., Smelter and concentrator.

Shannon Copper Co., Smelter and concentrator.

C Hayden:
American S. & R. Co., Smelter.
Ray Consolidated Copper Co., Concentrator.

D Superior:
Magma Copper Co., Concentrator.

E Wickenburg:
Vulture Mines Co., Cyanide mill.

F Humboldt:
Cons. Arizona Smelting Co., Smelter and concentrator.

G Goldroad-Oatman District:
Gold Road Mines Co., Cyanide mill.
Tom Reed Gold Mines Co., Cyanide mill.
New cyanide mills under construction at Oatman.

in the solution, and copper will be precipitated electrolytically.

The Copper Queen Consolidated Mining Company's smelting plant includes ten blast furnaces, sixteen six-hearth McDougal roasting furnaces, three oil-fired reverberatory furnaces and seven 13-ft. upright basic-lined converters. In 1915 the average tonnage smelted per blast-furnace day was 363.5; average product per roaster day, 47.5 tons of calcine; average daily reverberatory tonnage was 338.7, and copper bullion was made at the average rate of 32.6 tons per converter per day. Recent improvements made in overcoming dust losses at this plant are the subject of a paper to be presented at one of the Institute meetings.

2. Bisbee. Copper mines of the Copper Queen Consolidated Mining Co. will be open to inspection.

3. Globe-Miami District. The Inspiration Consolidated Copper Co. produces only copper concentrates, the ore containing small amounts of gold and silver, but too little to bring a commercial return to the company. The ore is a chalcocite disseminated through a schist gangue. The rate at which they are mining and milling at present is 16,000 tons per day, the largest output of mine to date for one day being 19,600 tons. The output of copper for the past two months has been 10,500,000 lb. per month. The run of mine ore is ground to pass a 48-mesh screen, after which it is subjected to flotation treatment, the sand tailings from flotation being further treated on concentrating tables. The concentrates are partially dewatered in Dorr tanks, and later put through Oliver filters. These concentrates are shipped to the International smelter, located 1 mile from the Inspiration mill, where they are smelted in reverberatory furnaces, the matte being treated in converters of the Great Falls type. The product is shipped to the Raritan, N. J., works of the International Smelting Company. Before going to the reverberatory furnaces the concentrates are put through a drying plant of Wedge furnaces. This drying plant is equipped with Cottrell dust collectors, and the converter gases are also passed through another Cottrell dust collector.

The International Smelting Co., which completed its plant at Miami in May, 1915, is a subsidiary of the Anaconda Copper Mining Company. It was designed, primarily, to treat the concentrates of the Inspiration Consolidated Copper Company and the Miami Copper Company. About 70 per cent of this material is a flotation product which is delivered to the plant in the form of a soft mud. After passing the dryers, it takes the form of an impalpable powder, so the handling of the original material and preventing mechanical loss later is rather difficult.

The plant has four principal metallurgical departments: I. Receiving, sampling, bedding and reclaiming. II. Drying. III. Reverberatory smelting. IV. Converting.

All fluxes and secondaries are crushed to at least $\frac{3}{4}$ in., and the proper mixture for smelting is made in the bedding bins.

Five fire-hearth Wedge mechanical roasters, 22 ft. 6 in. in diameter, burning oil, are in operation for drying and heating the charge. As it is not profitable to eliminate any of the sulphur, the temperature here is kept rather low.

Two oil-fired reverberatories, 21 ft. by 120 ft., with mechanism for changing the entire tonnage at the side walls, are in operation. Three 713-hp. Stirling boilers, in parallel, are used with each furnace. An extra furnace is in reserve.

At the converter plant are five stands with the 12-ft. Great Falls type of shells, two straight-line casting machines, and a McGregor skull-breaker.

The solid charge handled by furnaces per day is 1125

tons, 877 tons of which is concentrates. The copper content of the new material is 281.5 tons, with 9 ounces of gold and 780 ounces of silver, producing 275 tons of copper, 8 ounces of gold and 700 ounces of silver.

The property of the Miami Copper Company, located 7 miles west of Globe, Ariz., comprises an ore body of chalcocite disseminated in schist, a combined water and flotation concentrator, a concentrate-handling plant, a reclaimed-water plant and a fuel-oil power plant. The current production is about 50,000,000 lb. of copper per annum.

The ore body is composed of Pinal schist, intermixed with granite porphyry and overlain by about 200 to 300 ft. of silicified capping. The mineral occurs as partially oxidized chalcocite finely disseminated throughout the schist and porphyry. The present ore reserves are about 18,000,000 tons of high-grade sulphide ore, averaging about 2.40 per cent copper and 17,000,000 tons of low-grade primary ore. Mining is conducted by underground workings, using shrinkage stoping and top slicing methods. The ore is hoisted by balanced Kimberly skips of 7-ton capacity from a depth of 400 and 500 ft.

The concentrator is of steel and concrete construction, and comprises a coarse-crushing plant and six independent grinding and concentrating sections, with an initial capacity of 3000 tons of ore per twenty-four hours, which has been increased to 5000 tons. Coarse-crushing is performed by Kennedy gyratory crushers and Traylor rolls, and fine grinding by Hardinge conical ball mills. Concentration is performed with Deister sand and slime tables, followed by flotation, using Callow flotation cells. Ratio of concentration is about 25 to 1.

Water for concentration is obtained from the Old Dominion mine, 7 miles distant, and is partially reclaimed by means of sixty-four concrete settling tanks. About 75 per cent of the water used in milling is thereby reclaimed.

Concentrates are laundered to a concentrate-handling plant, comprising twelve vacuum dewatering tanks. Belt-conveyors communicating with these tanks transfer the concentrates, after drying, to 60-ton steel concentrate cars for shipment to the neighboring plant of the International Smelting Company.

The power plant, located adjacent to the town of Miami, is a steel and concrete structure, and comprises a boiler plant containing five batteries of 600-hp., oil-fired boilers, and an engine house containing three 1000-kw., triple-expansion engines, two 4000-cu. ft., triple-expansion air compressors, and condensing apparatus.

The Old Dominion Copper Mining & Smelting Co. has a new 700-ton concentrating mill which was put in operation about two years ago. As a result of the improvements made in the new plant the percentage recovery of copper was raised from 73.55 in 1914 to 85.27 in 1915. Grinding is done with Hardinge conical and Marathon mills; pulps are classified in Deister cone classifiers and concentrated on Deister tables and Senn pan-motion vanners. A 16-cell, 300-ton Minerals Separation flotation machine has been in use for some time, and other types of flotation apparatus are being tested. An Oliver filter is used to dewater the flotation concentrate. The smelting plant consists of blast furnaces only. The Great Falls type of basic-lined converter is used, and a remarkable cost record has been made. One shell was in service continuously for over thirty months, producing 70,860,000 lb. of copper bullion. The lining cost was 5 $\frac{1}{2}$ cents per ton of bullion, as compared with a cost of \$1.80 per ton with the old acid-lined shells. A feature of the power plant is a Diesel oil engine and generator.

X. Ray. Ray Consolidated Copper Co. mines may be visited on a side-trip from Globe. The company's mill is at Hayden, near the smelter of the American Smelting & Refining Company.

Z. Jerome-Clarkdale District. This region of Arizona is prominent through the operations of the United Verde Copper Co., with mines at Jerome and a new smelting plant at Clarkdale. The capacity of the Clarkdale plant is about 3000 tons of charge daily, and production amounts to 5,000,000 pounds of copper per month, in which is contained a small amount of gold and silver. The principal metallurgical departments are (1) crushing and sampling; (2) roasting; (3) blast-furnace and reverberatory smelting; (4) converting. The roasting equipment comprises eight 6-hearth Wedge roasters, 21 ft. 6 in. diameter. In the smelting department there are four 48 in. by 320 in. blast furnaces with Giroux hot-blast tops, and three 19 ft. by 100 ft. oil-fired reverberatories. The converting equipment consists of five stands of 12-ft. Great Falls type basic-lined converters. Further data on the operation of this plant will appear in a later number of this journal.

The Copper Chief mine, operated by the Hayden Development Co., near Jerome, has a new cyanide mill of 125 tons daily capacity. Ore is crushed by Blake crusher, ball and tube mills, the latter in closed circuit with a Dorr classifier. Continuous counter-current decantation is practiced, using Dorr agitators and thickeners with Oliver filters at the end of the system. The customary zinc boxes are used for precipitation, and the product is melted in a Steele-Harvey furnace. The entire mill is electrically driven by power obtained from the Arizona Power Company's plant at Fossil Creek.

Other Metallurgical Centers

A. Pearce. The cyanide mill of the Commonwealth Mining & Milling Co. is located here. Ore is crushed first in gyratories and then thirty 1550-lb. stamps. Classification is given in Caldecott cones and Dorr classifiers, and further grinding is done in Hardinge conical mills and tube-mills. Continuous counter-current decantation is practised, using Dorr thickeners and Pachuca agitators. Oliver filters and Merrill zinc-dust precipitation complete the equipment.

B. Clifton-Morenci-Metcalf District. Three large copper companies operate in this important district. The Arizona Copper Co. has concentrating and smelting plants which will be the subject of a paper to be presented at one of the technical sessions.

The Detroit Copper Mining Co. produces about 19,000,000 pounds of copper annually. Run of mine ore is reduced by one Gates gyratory crusher and two Symons disc crushers to 1-in. size. This product is fed at the rate of 1500 tons to the two-unit concentrator.

The mill feed is reduced by rolls to pass a four-mesh screen and is then treated to a succession of wet concentrations as follows:

Total mill feed through four-mesh is treated on Butchart national tables, the tailings of which are deslimed in shovels. The fine product (slime) of these shovel wheels is primary slime. The coarse product is reduced to $1\frac{1}{2}$ millimeter by means of Monadnock and Marathon mills. The product of these mills is separated by means of Dorr classifiers into coarse sand, fine sand and slime; the coarse sand is treated on Butchart National tables, the fine sand on Frue sand vanners, and the slime overflow, united with primary slime mentioned above is treated by flotation machines of the Rork type.

Flotation reject is cleaned up by a system of Frue

sand vanners. Total mill concentrates are dried by vacuum tanks and shipped to smelter. The tailings are dewatered in Dorr tanks and the clear water returned for further use.

Concentrates are delivered to the smelter which consists of one 500-ton blast furnace. The matte is then delivered to three barrel-type converters. The product is sold as casting copper.

The Shannon Copper Co. is the third concern operating in this district and has a copper concentrating mill and smelting plant.

C. Hayden. The American Smelting & Refining Co. operates a smelting plant of 25,000 tons monthly capacity, producing 8,000,000 lb. blister copper per month. The bullion contains some gold and silver. The principal departments are sampling, roasting, reverberatory smelting and converting. The equipment consists of eight McDougall roasters, two reverberatory furnaces, two Peirce-Smith and one Great Falls type converters and one Walker casting machine.

In the same vicinity is the concentrating mill of the Ray Consolidated Copper Co., which is about 18 miles distant from the mines at Ray. The present capacity is 10,000 tons per day, and the principal metal is copper, although the ore contains a small amount of silver. Coarse crushing to 1-in. size is done at the mine and further reduction is made at the mill with Garfield rolls and Chilean mills. Concentrating equipment consists of Garfield roughing tables, Wilfley tables and slime vanners.

D. Superior. At this point the Magma Copper Co. is conducting experimental operations in the concentration of copper and zinc ores. The copper concentrator is handling about 200 tons of ore per day which is delivered from the mine by a Bleichert aerial tramway. A variety of crushing and grinding machines are in use, comprising Blake crusher, Symons 24-in. disc crusher, Marcy ball-mill and Chalmers & Williams tube-mill. The crushed pulp is concentrated over roughing tables, and by flotation in Callow pneumatic cells. The tailings from the latter are reconcentrated on Wilfley tables. The 50-ton zinc concentrator uses the same types of crushing and grinding apparatus, Callow flotation cells and Deister double-deck tables.

E. Wickenburg. The cyanide mill of the Vulture Mines Co. gives some distinction to this point in Arizona by reason of having been one of the first to make a commercially successful use of the continuous counter-current decantation system of cyaniding. More modern mills have since used the process in greater refinement. This plant is small, having a capacity of but 75 tons per day.

F. Humboldt. The Consolidated Arizona Smelting Co. has copper smelting and concentrating plants at this place. The concentrating equipment and practice were discussed in this journal, Dec. 1, 1915, p. 897. Data on reverberatory smelting appeared Jan. 1, 1916, p. 33. Improvements in both plants have been made since that time, increasing capacity and efficiency. The introduction of flotation, together with other changes in the mill, increased recovery of copper by more than 20 per cent over the best saving previously made with jigs, tables and vanners.

The principal features of the mill, described in the article mentioned above, are grinding with Hardinge mills and the use of the Minerals Separation flotation process. The smelting equipment consisted of one 7-hearth Wedge roaster, 21 ft. 6 in. diameter; one 19 ft. by 60 ft. and one 19 ft. by 100-ft. oil-burning reverberatory furnaces; two stands of 9 ft. 6 in. barrel-type basic-lined converters.

G. Goldroad-Oatman District. This part of Arizona has recently attracted considerable attention by reason of the remarkable discoveries of gold and silver ore in a region where two companies had operated for a number of years. The **Gold Road Mines Co.** has a 350-ton cyanide mill, using stamps and tube-mills for grinding, and continuous counter-current decantation with Dorr thickeners and Pachuca agitators. Precipitation is by means of zinc dust. The **Tom Reed Gold Mines Co.** at Oatman has a similar mill of 200 tons daily capacity, with practically the same equipment. Among the newer mills projected in the Oatman district is that of the **United Eastern Mining Co.** The tentative flow-sheet shows crushing with gyratories, ball-mills and concave mills, the latter in closed circuit with Dorr classifiers. Continuous decantation with Dorr apparatus follows the latest developments in that method of cyaniding, and precipitation is to be done by the Merrill zinc-dust process.

The Training of Our Captains of Industry*

BY SIR ROBERT HADFIELD

A good deal has been said, particularly in the last few months, with regard to the training of men on whom rest the responsibility to organize and direct the technical side in great industrial affairs. In my opinion neither the scientific man nor the practical man wholly fulfills the required conditions for the direction of great modern affairs. By the practical man I mean the man who has received a good secondary education, but not special scientific culture, and by the scientific man I mean the man who is completely instructed, but is a stranger to actual experience and practice.

It usually happens that the scientific man is as necessary as the practical man, but neither the one nor the other is a satisfactory organizer, because they do not unite in one head the combination of the two indispensable elements. It is therefore necessary to arrange our educational courses so as to combine the two; in other words, to find a third type of man in whom such knowledge will be united. The solution of the problem is not easy, but it is more than ever necessary that at the present time such a new type should be evolved and developed.

Until quite recently many mistakes were made, either because the scientific man had been installed in view of his special knowledge or, at the other end of the scale, the practical man was given the preference. In a general way neither of these types has been a success.

Industrial operations of every kind, and of an increasingly complex character, are developing every day, and they are also tending to be more and more technical. This is the normal consequence of the extremely rapid progress which every nation is making in the acquisition of knowledge, which in itself is constantly becoming more varied, and yet more specialized.

It is most difficult to map out a program of education which will combine both scientific and practical ideas, especially as the main functions of each of these are sufficiently defined and naturally fall into their respective spheres. The scientist has a satisfactory education in the universities. The practical man is generally contented with an ordinary high school education, and sometimes, as is well known, he has not even had the benefit of this general education.

The scientist can certainly do excellent work in his laboratory, but generally speaking, he will only be able to render these services in this one capacity, because he has not had the opportunity to adjust his theoretical

knowledge to industrial conditions. The practical man also in his vocation is able to do good work, but it is doubtful whether in these days he can ever furnish work of the highest order.

How then are we to obtain this important combination? How can we realize the combination of science and practice? The problem is admittedly most difficult, and the solution of it probably depends in a large measure on the individual character. By means of character and energy the scientist can acquire practical knowledge; that is, he can apply his scientific knowledge to practical questions. In the same way, the practical man can acquire scientific knowledge. Education will certainly help the formation of this mixed type, but it will not be created by education alone. It must be a result either of natural temperament, of faculties developed by force of character, or in certain cases through gifts transmitted by heredity.

Naturally the best path to follow is that of scientific education, but on condition that instruction furnished by practical observation is not neglected.

All things considered, the scientist will certainly be in a better position, but if he does not possess the necessary turn of mind and the natural qualities to which reference has been made, this education which should have given him a great advantage may cause his ruin. It may prevent him from attaining the height of success to which he might have reached by applying his knowledge to practical ends. He remains in the same sphere, and cannot emerge therefrom. Numerous are such cases, and numerous also the instances of non-success among men who are practical, in consequence of their lack of scientific knowledge.

While much has already been done, there is much more to be accomplished in order to succeed in generating the evolution of the type of man required by modern conditions. Many facilities are offered to the practical man by the creation of the numerous and liberally endowed sources and seats of instruction which have been installed in all countries during the last twenty-five years. There has been the work of our universities, also of the departments of applied science attached to those universities, of our schools and technical colleges, of our research laboratories, our societies and technical institutions, and finally our technical press. All these are, in this order of ideas, of capital importance.

The combination of science and practice is of the greatest importance, but it is doubtful whether it can be obtained by education alone. In order to attain the highest degree of success a man requires something even more than education; that is, above all he must show personal application and intuition.

As so much attention is being given to a wider application and more intimate combination of science with industrial research, a few special remarks may be made with reference to this side of the subject, and in this respect attention is specially drawn to the admirable advice given by the late Dr. G. Gore, F.R.S., in his book, "The Art of Scientific Discovery."

Dr. Gore himself did most important research work. For example, it was he who discovered that iron, while cooling from a high temperature—then termed "red heat," now known as the "critical iron changing point"—about 750 deg. C., and under longitudinal strain, suddenly undergoes molecular and magnetic change attended by increase of length at a particular time. This peculiar behavior of iron has been termed "Gore's phenomenon." From Gore's observations of this simple fact eventually sprang the further discovery of Sir William Barrett, F.R.S., with regard to the recalcrescence of steel, which was further followed up by the late Prof. F. Osmond in France, with such important results.

*From *The Iron and Coal Trades Review* (London) of June 9, 1916.

Gore shows in his work above referred to that scientific discovery is really no haphazard matter, and that the art can be cultivated. While all may not have the same mental capacity, there are many who, by scientific study, may acquire the art to a greater or lesser degree. There is, of course, some difference between discovery and invention. Gore defines it as follows: "Discovery consists in finding new truths of Nature, while invention consists in applying those truths to some desired purpose." However, for our present purpose the two may be treated more or less on an equality. Gore points out, while he does not maintain, that important discoveries can be made by rule alone; nevertheless the process of scientific discovery can be largely reduced to order and rule. It may be interesting to note the following types of research tabulated by Gore and through which discovery and invention may be attained:

Table by Dr. Gore Showing That Discovery and Invention May be Obtained in Some of the Following Manners:

- (1) Aid to Analogy.
- (2) Hypotheses.
- (3) Analysis and Synthesis.
- (4) Application of—
 - (a) Electricity to bodies.
 - (b) Heat to substances.
- (5) Asking questions and testing such questions.
- (6) Assumptions that—
 - (a) There is a certainty of all the great principles of science.
 - (b) Complete homologous series exist.
 - (c) Converse principles of action exist.
 - (d) Certain general statements which are true of one force or substance are true to some extent of others.
- (7) Combined action of many observers.
- (8) Comparisons of—
 - (a) Facts, and collecting similar ones.
 - (b) Collections of facts with each other.
 - (c) The orders of collections of facts.
 - (d) Facts with hypotheses.
- (9) Deducting process.
- (10) Employment of new or improved means of observation.
- (11) Examination of—
 - (a) Common but neglected substances.
 - (b) Effects of forces on substances.
 - (c) Effects of contact on substances.
 - (d) Effects of extreme degrees of force.
 - (e) Extreme or conspicuous instances.
 - (f) Influence of time upon phenomena.
 - (g) Neglected truths and hypotheses.
 - (h) Peculiar minerals.
 - (i) Unexpected truths.
 - (j) Rare substances.
 - (k) Residue phenomena.
 - (l) Residues of manufacture.
 - (m) The ashes of rare plants and animals.
- (12) Extension of—
 - (a) The researches of others.
 - (b) The researches of neglected parts of science.
- (13) Inductive process.
- (14) Investigations of—
 - (a) Exceptional cases.
 - (b) Unexplained phenomena.
 - (c) Classification unexplained.
- (15) Means of—
 - (a) Converse experiments.
 - (b) Hypotheses.
 - (c) "Homologous Series."
 - (d) Instruments of great power.
 - (e) Improved methods of intellectual operation.
 - (f) Measurements.
 - (g) The method of curves.
 - (h) The method of least squares.
 - (i) The method of means.
 - (j) The method of residues.
 - (k) New instruments.
 - (l) Modes of observation.
 - (m) Observations.
 - (n) More intelligent and acute observation.
 - (o) Additional observations by known methods.
 - (p) Periodic functions.
 - (q) More refined methods of working.
 - (r) Repetition of experiments.
- (16) Simple comparisons of facts of phenomena.
- (17) Search for—
 - (a) So-called "impossible" things.
 - (b) One thing and finding another.
- (18) Subjecting series of forces or substances to new conditions.
- (19) Use of—
 - (a) Known instruments or forces in a new way.
 - (b) Improved instruments.
 - (c) More powerful instruments.
 - (d) Causes by the methods of averages.
 - (e) Coincidences.
- (20) Conditions of—
 - (a) Scientific discovery.
 - (b) Determination of the nature of a discovery contrasted with barren reasoning.
- (21) Experimentation of discovery upon art of exceptional instances.
- (22) Fundamental laws of discovery.

The word "discovery" naturally suggests "What led Columbus to discover America?" His deductive capacity must have been very great, and no doubt mentally he must have gone through more than one of those phases

described in the tabular statement arranged by Gore. The expedition of Columbus was no happy-go-lucky one, but made with a definite purpose founded on certain definite facts known beforehand. It is interesting to remember that while on his voyage of discovery and founding another continent, Columbus discovered many curious facts with regard to compass variation.

In concluding these remarks the writer of this essay hopes that at any rate some of the ideas and suggestions put forward may lead to a better understanding of what is in these modern times required to be borne in mind in the training of those who are going to be our captains of industry, also of the channels through which discovery and invention are likely to be brought about.

The Nitrate Situation

Report of Committee on Public Relations of American Electrochemical Society

The Committee on Public Relations of the American Electrochemical Society has sent the following recommendations to the President, the Secretary of the Navy, and the Secretary of War:

Inasmuch as the utilization of atmospheric or other sources of nitrogen to supplant Chilean nitrate in this country for the manufacture of explosives and as a source of fixed nitrogen for fertilizers is in many respects an electrochemical problem, the undersigned members of the Committee on Public Relations of the American Electrochemical Society, constituted of the president and past-presidents of the society, feel justified in making the following statements and recommendations:

1. We urge upon this government the necessity of providing at once eighteen months' supply, on a war basis, of Chilean nitrate, using government ships if necessary, this reserve to be stored at various strategic points.

2. Almost all of those who have intimate knowledge of the practical working of nitrogen processes are in one way or another associated with some particular process, and we know of no experts who could be considered as having a strictly unbiased mind on the subject, as the government should be in possession of accurate confidential information regarding present developments in each of the processes proposed to date in order to be able to act wisely and promptly in case of sudden emergency, we add our indorsement to the recommendation already made by the Naval Consulting Board and others, that a small committee of appointees by the President be delegated to visit each of these groups of men who control these processes and who have already intimated their willingness to furnish proper representatives of the government with full confidential data.

3. As we confidently hope that this country may never be involved in war, while thoroughly believing it should be prepared for immediate defense, it should be remembered that the great peace use of fixed nitrogen is as a plant food, and it is therefore desirable that private interests be allowed to develop the best and cheapest process on a peace basis without either government aid or government hindrance unless equally applied to all comers. We are therefore opposed to a government subsidy to any particular process at the present time, or the immediate construction of a government plant working any particular process. All of the processes can apparently be greatly improved, and the evolution of the best process will proceed more rapidly than under the artificial stimulation which government backing would give to any single process. The purchase of a suitable supply of Chilean nitrate and the possession of information upon which to base an emergency decision

advocated above will serve the purpose of military expediency without discouraging private initiative. We are, however, in favor of a liberal water power policy, as the question of the cost of power is vital to several of the processes. We believe it is in the highest degree conserving resources to make use of the otherwise wasting water power which can be conserved in no other way, and thereby preserving other sources of power, as coal, gas and oil.

4. The processes to be considered may be classified into those which produce nitric acid by direct union of the nitrogen and oxygen of the air, such as the Birkeland-Eyde and the Pauling processes; those which produce ammonia by direct union of nitrogen and hydrogen, such as the Haber process; those which fix nitrogen in a complex compound, such as the cyanamid process, and the action of nitrogen fixing bacteria in natural fertilization, and, finally, natural sources of fixed nitrogen, the only one which is of sufficient magnitude to warrant consideration is by-product ammonia derived from the distillation of coal. All of these, except the arc processes, produce ammonia, and as this and not nitric acid is the chief desideratum for fertilizer purposes, there is not sufficient commercial incentive for the carrying of these ammonias of varying degree of purity through the nitric acid required in the manufacture of explosives. All of the processes except that involving the use of bacteria have more or less active exponents in this country. We therefore urge that the research facilities of the government be concentrated upon these two points: The oxidation of ammonia and the *modus operandi* of nitrogen-fixing bacteria. This could be done with the aid of some of the government departments. Thus the Bureau of Mines should be able to investigate the oxidation of ammonia while the fixation of nitrogen by bacteria might be well studied by the Bureau of Soils.

The Western Metallurgical Field

Geological Survey's Mid-Year Review

Following a practice begun last year, the U. S. Geological Survey has issued a mid-year review of the mineral industry, showing the remarkable accomplishment of the first six months of 1916. From these indications the forecast is made that 1916 will be a record-breaking year. Coal, iron and steel, cement and oil have experienced unusual demands, and large gains over last year's records are easily foreseen.

Most precious-metal mines are operating at full capacity. The gold production will probably fall below the high yield of last year, but silver, the one metal last to benefit by the general domestic prosperity, is expected this year to break all previous records.

In Colorado the gold production of Cripple Creek, which accounts for 60 per cent of the State's output, has fallen off appreciably, and the San Juan region has not maintained its output of 1915. From California it is reported that the U. S. Mint and local smelters and refiners are in receipt of \$366,000 less gold and 22,000

more ounces of silver during the first five months of 1916 than in the corresponding period a year ago. Nevada also will likely show a decrease in gold, due to declining production at Goldfield and the failure to discover new important deposits. Bullion receipts from Oregon mines show an increase in both gold and silver, the former being due entirely to dredging operations.

Copper is continuing the steady increase in production which began early last year, and the forecast for 1916 indicates not only the largest output ever known but also the largest profits. In Nevada the copper output has been increased more than 50 per cent, and the value at present prices will be double that of last year. Arizona will continue to hold first place among copper-producing States, producing 600,000,000 lb. of copper if production continues at present rate, which is nearly double that of any other State. In Utah the probability is that the year's production of copper will be 225,000,000 lb. The value of copper produced will be about double that of 1915.

The lead and zinc mines are producing ore at a rate even exceeding that of last year, and the prevailing prices have made possible the working of large quantities of low-grade ore. From Idaho shipments of lead are being made at the rate of 360,000,000 lb. per annum, and there will be a corresponding increase in the output of silver. Coeur d'Alene companies are shipping lead concentrates and ore at the rate of over 30,000 tons a month, and zinc material at the rate of over 8000 tons a month. No great increase in zinc is looked for in Utah, but Colorado is expected to exceed the record of 1915.

In quicksilver the outlook is for a continuance of the output of 1915, which was the largest for several years. Thus far in 1916 the average price has greatly exceeded the 1915 prices; and although the reaction in prices has come, conditions are favorable for steady and profitable operation of the quicksilver mines, some of which are newly opened.

Shipments of iron ore from Lake Superior points for five months of 1916 exceeded by more than 80 per cent those for the same months in 1915, and the indications for the year are favorable for a new high record on iron-ore production, and of pig iron as well. Higher prices with a steady demand are stimulating the mining of manganese, with the result that this year's output of ore is expected to surpass the large production of last year.

Electrolytic Zinc in Utah

Construction of the new electrolytic zinc plant for the Judge Mining & Smelting Co., at Park City, Utah, is progressing satisfactorily, the excavation and foundations having been completed. The work is being pushed with vigor in order that production may begin at an early date. When the new plant is completed it will handle about thirty tons of high-grade zinc concentrates per day and turn out about fifteen tons of electrolytic zinc. It is reported that a feature of the electrolytic work will be the use of revolving cathodes of aluminium. While other experimental work has been done on electrolytic zinc in Utah, the Judge plant will be the first to operate on a commercial scale.

Production of Platinum in California and Oregon

An increase in the production of crude platinum in California and Oregon in 1915 is reported by the U. S. Geological Survey. The official figures show an output of 741.91 troy ounces, valued at \$23,538. This is an increase of 171.91 ounces over the production in 1914. California is the principal producer, only one mine in Oregon reporting any output. Platinum refiners report that a total of 8665 troy ounces of new

metals of the platinum group was recovered, of which at least 1587 troy ounces is believed to be of domestic origin.

Secondary metals derived from the refining of scrap and sweeps to the amount of 42,970 troy ounces were sold in 1915.

Notwithstanding the embargo placed upon the exportation of platinum by all the allied governments, the United States imports of platinum and allied metals during the year 1915, as compiled by the Bureau of Foreign and Domestic Commerce, Department of Commerce, were only 10 per cent below the 1914 imports, amounting in all to over 69,000 ounces, having a value of \$2,768,688.

Figures showing the world's production of platinum and allied metals are at best estimates made from the most reliable information obtainable. The table below gives the best estimates from information available to the Geological Survey at this time:

Country	1912	1913	1914	1915
Borneo and Sumatra	200	200	(*)	
Canada	30	50	30	100
Colombia	12,000	15,000	17,500	19,000
New South Wales	778	1,275	1,248	856
Russia	300,000	250,000	241,200	124,000
United States	721	483	570	742
	313,729	267,008	260,548	143,898

*No basis for estimate.

†No figures from Tasmania available at time report goes to press.

Teck Hughes Cyanide Mill, Ontario

The Teck Hughes property in the Kirkland Lake district of Ontario is equipped with a 50-ton cyanide mill of the continuous decantation type. Primary crushing is done with a 16 in. by 10 in. jaw breaker of the Blake type, and subsequent grinding by a 5 ft. by 5 ft. ball mill. The ball-mill discharge is further ground in a 5 ft. by 20 ft. tube-mill running in closed circuit with a Dorr classifier. The slime thus produced is treated by continuous agitation and decantation in Dorr agitators and thickeners. A change of solution is made after agitation is two-thirds complete, in accordance with practice which has been explained at length in former articles in this journal. The thickeners are of the tray type which have been proving popular in recent installations. Due to the high grade of the ore and relatively high strength of cyanide solutions, a filter of the Oliver type follows the decantation system as is customary under such conditions.

Some Unusual Conditions in Oklahoma Zinc Mines

An occurrence of hydrogen sulphide in the new zinc mines of the Picher Company at Picher, Okla., constitute an unusual phenomenon that has caused some trouble in mining operations. The characteristic odor of the gas is plainly perceptible about the shafts and in the workings, and water pumped from the mines is milky with precipitated sulphur. The effect on the workmen is such that they are unable to put in a full shift without relief. Practically all the miners become affected with what is locally known as "pink eye," an affection of the membranes of the eye that causes inflammation and discomfort. In some cases the affection is so acute that the men can work only during alternate two-hour periods. Various remedies have been used, but one of the best that had been tried was the wearing of goggles that keep the gases from the eyes. The workings are ventilated by blowers and exhaust fans, the former at the shafts and the latter at drill holes connecting with the drifts. As far as is known the occurrence is localized at the properties mentioned.

Another unusual condition is encountered at the property of the Admiralty Company near Cardin. Here the ore is impregnated with a natural hydrocarbon that gives considerable trouble in milling. The ore is black in appearance and has a strong odor of mineral oil. The concentrates also have an oily appearance and odor. The chief difficulty encountered in milling was due to the clogging of the jig screens by the hydrocarbon material. This has been overcome by introducing kerosene under the screen of the first compartment of the jig, thus "cutting" the heavy oil and keeping the screens clear. Several barrels of kerosene are used per day, fed under pressure from a reservoir in the hoist house. Other oils were tried, such as gasoline, but kerosene proved most effective.

Production of Gold and Silver in the United States

The Bureau of the Mint and the Geological Survey have issued the following joint statement as to the final figures on the production of gold and silver in the United States during the calendar year 1915:

State or Territory	GOLD		SILVER	
	Fine Ounces	Value	Fine Ounces	Value ¹
Alabama	247	\$5,100		
Alaska	808,346	16,710,000	1,054,634	\$526,100
Arizona	220,392	4,555,900	5,665,672	2,826,500
California	1,090,731	22,947,400	1,830,024	843,100
Colorado	1,089,928	22,530,800	7,199,745	3,591,900
Georgia	1,628	34,800	141	100
Idaho	56,684	1,170,600	13,042,466	6,506,800
Illinois			2,892	1,900
Michigan			581,874	290,300
Montana	240,825	4,078,300	14,423,173	7,195,600
Missouri			35,334	27,700
Nevada	574,874	11,883,700	14,438,085	7,210,500
New Mexico	70,632	1,460,100	2,337,064	1,165,900
North Carolina	8,258	170,700	1,496	700
Oregon	90,321	1,867,100	125,499	62,600
Philippine Islands	63,898	1,320,900	15,145	7,600
Porto Rico	34	700		
South Carolina	174	3,600		
South Dakota	358,145	7,403,500	197,569	98,600
Tennessee	329	6,800	99,171	49,500
Texas	87	1,800	724,580	361,500
Utah	189,045	3,907,900	13,073,471	6,522,200
Vermont			150	100
Virginia	24	500		
Washington	22,330	461,600	213,877	106,700
Wyoming	672	13,900	2,910	1,400
Total	4,887,604	\$101,035,700	74,961,075	\$37,397,300

¹At the average price of silver per fine ounce for the calendar year 1915, \$0.49880.

These figures compare with the production of 1914—\$94,531,800 in gold and 72,455,100 fine ounces of silver, being a gain in the gold production of \$6,503,900 and 2,505,975 fine ounces in the silver product.

Company Reports

Alaska Gold Mines Co. made a profit of \$251,848 in 1915, being 22.581 cents per ton treated. Miscellaneous income of \$26,923 is to be added. The first section of the mill began operations on February 12, 1915, and the full average tonnage of 6000 tons per day was maintained by November. Steps were taken to increase the capacity to 12,000 tons per day. During the year 1,115,294 tons of ore was milled, having an average value of \$1.1569 per ton. Average tailings were 21.91 cents, showing an extraction of 81.06 per cent. Average total milling cost for the year was 30.496 cents, though in November the cost was but 25.699 cents. Average total net cost for the year in mining, milling and disposition of products, inclusive of all fixed and general charges was 69.039 cents per ton. The same cost in November was 59.785 cents.

Butte & Superior Copper Co. had an operating profit in 1915 of \$9,074,151, with miscellaneous income of \$51,795, making a total of \$9,125,946, as compared with \$1,417,127 in 1914. Dividends paid amounted to \$4,908,115. Under the company's contract with the American Zinc, Lead and Smelting Co., the spelter

produced from Butte & Superior Concentrates is returned to the original company for sale in open market. Owing to the fact that the word "Copper" in the company's name is misleading, and inasmuch as the chief product is zinc it is proposed to change the name of the concern to Butte & Superior Mining Co. Developed ore reserves at the end of the year were about the same as a year previous, and amounted to about 1,000,000 tons. Total ore mined amounts to 522,949 tons at an average cost of \$3.36 per ton. The flotation plant was rebuilt for the purpose of increasing capacity and increasing efficiency. An increase in capacity 60 per cent greater than in 1914 was brought about without extensive additions to plant. Total ore milled amounted to 522,300 tons, but late in the year the average was 50,000 tons per month or at the rate of 600,000 tons per year. Average zinc content of ore milled was 17.02 per cent; of silver, 7.63 ounces per ton. Mill recovery averaged 92.21 per cent, but for the last quarter it was 95.07 per cent. Average cost of milling was \$1.75 per ton, as compared with \$2.12 for 1914.

The Iron and Steel Market

The steel market has turned distinctly stronger in the first half of August, a reflection in part of the remarkable stability it showed during June and July when in the face of very light demand prices were held very firmly and the mills appeared to be quite indifferent as to whether or not they booked additional business, and a reflection also of the heavier demand for shell steel than had been expected.

The new development of August is that resistance to weakness has given way to a positive exhibition of strength. The new movement started with the official announcement on the afternoon of August 1 that the Carnegie Steel Company had advanced its price on merchant steel bars \$2 a ton, from 2.50c. to 2.60c. The independents began quoting the advanced price in a limited way, while they closed at 2.50c. such pending negotiations as could be brought to a head, and the market is now practically established on the higher basis. Structural shapes showed a tendency to move up in harmony with bars even though on account of the peculiar alignment of demand for different products at this time the demand for shapes is relatively light while the relative demand for bars is abnormally heavy. Plates are now predicted for a rise also, and wire products are moving upwards.

Buying of steel in the domestic market goes by movements and a movement must have an exciting cause, such as price advances or mills falling farther behind in deliveries. The last buying movement began to wane in March and came to an end in May, since which time the buying has been spasmodic and sporadic in character. At the beginning of June the balance of probability seemed to be that there would not be another buying movement until there had been a readjustment in prices, and in some quarters it was thought far from improbable that the market would weaken toward the close of August or in September, not because the large mills would not get additional business but because the small mills presumably would, since customarily they do not sell far ahead. The small mills are now found to be in strong position, however. As time has passed predictions have begun to appear that a fresh buying movement of some proportions would start in the fall, presumably in September, and the events of the past fortnight have tended to strengthen the expectation.

Export and War Demand

A strong factor in the further stiffening in the steel situation has been the unexpectedly heavy demand for

steel for export and for shell manufacture. There was heavy buying of shell steel in April and May and at the close of May it was rather thought that substantially all the business for the second half of this year had been placed. The buying has, however, continued on a large scale. In the past thirty days it appears that more than half a million tons of shell steel has been placed, with negotiations for a considerable tonnage still pending. The recent business involves a larger percentage of shell steel to be shipped abroad in the form of rolled rounds and forging billets, as the capacity for making shells abroad, particularly the smaller shells, has been rapidly increasing. There is a large decrease in the manufacture of small shells in the United States, but the manufacture of large shells is increasing, and on the whole it would appear that the production of shell steel is increasing, though possibly a somewhat smaller tonnage will be converted into shells in this country.

Apart from this movement in shell steel there is continued heavy demand for soft steel for export, apparently because the steel works abroad are diverting more of their capacity to the manufacture of shell quality, involving a greater call upon the United States for soft unfinished steel. As a result of these conditions the market for soft steel billets and sheet bars is a trifle stronger than at any previous time in this movement.

Production Decreased

Since the first of July the production of pig iron has been at a rate of about 38,250,000 tons a year, contrasting with the high rate of 39,800,000 tons attained in May. The chief factor in reducing the output has been the extremely high humidity, much above the normal even for July and August. A smaller but hardly a negligible factor has been the necessity of blowing out quite a number of furnaces for relining, more furnaces having gone out since July 1 than have gone in. It is quite evident that the furnace performance last spring was abnormally good and it seems certain that the existing furnaces cannot for a twelvemonth maintain an average rate of 40,000,000 tons. The maximum rate attained before this movement was 34,000,000 tons, in March and April, 1913, and not more than half the increase in the rate to last May can be attributed to the completion of new furnaces. Scarcely any new stacks will come in during the balance of this year and while about twenty-five new furnaces are being built it seems improbable that all will be completed by the end of 1917.

The very hot weather has decreased steel mill operations more than pig iron output, the production of finished steel being reduced, from the June rate, by more than 10 per cent, and thus pig iron has not grown scarcer, though it may do so later in the year.

Pig Iron

Pig iron has been stagnant in all districts, buyers apparently being well covered. Occasionally interest is manifested in foundry iron for the first quarter or first half of 1917 but the furnaces are indisposed to quote, feeling that the balance of probability is that prices will be higher later in the year. In some quarters a buying movement is predicted for September, chiefly on the ground that as steel making capacity is being increased by various additions there will be more iron needed than has already been provided. Some of the large steel interests, normally self-contained, may enter the market.

Steel

Soft steel is strong at a general level of about \$45 for either billets or sheet bars. While Bessemer may be

a shade lower than open-hearth there seems to be little distinction at this time. Rods are \$55 to \$60, with high carbon rods commanding unusual premiums over mild steel grade.

Production of Tin Plate and Galvanized Sheets

Statistics have just been made public showing the production in 1915 of tin plates, terne plates and galvanized sheet products, the comparison being as follows, in gross tons:

	Tin Plate	Terne Plate and Terne	Total Tin and Terne	Galvanized Sheets	Galvanized Formed Products
1912	962,971	61,134	823,719	824,047	51,674
1914	865,978	65,286	931,241	806,994	58,752
1915	982,958	72,978	1,055,936	706,058	50,119

The previous record year for tin and terne plate production was 1912, with 962,971 tons. The decrease in galvanized sheet production in 1915 is less than would have been predicted as the high-priced spelter reached before the middle of the year eventually caused a large decrease in galvanizing operations. The mills evidently operated on relatively cheap spelter for a while after the top was reached in the spelter market in June.

The Non-Ferrous Metal Market

Copper.—There has been little doing in the past two weeks in copper. The market remains firm, however, as it is pretty well sold up. Electrolytic was quoted on Aug. 11, at 26.50c. for spot and August deliveries, New York, with futures at 26c. Lake is quoted at 26.75c. spot.

Tin.—This market has been generally quiet. There is a large supply of Banca tin on hand which was quoted on Aug. 11, at 36.25c. New York, when Straits was held at 37.67½c. for spot. Deliveries to consumers in July amounted to 4432 tons.

Lead.—On Aug. 2 the American Smelting & Refining Company reduced its price from 6.50c. to 6 cents New York, a reduction which was generally expected, and which was thought would bring large business. The reduction did not stimulate buying to any great extent, however. Independents are asking 5.95c. New York.

Spelter.—This metal is dull and weak with little business done. Spot spelter was quoted on Aug. 11 at 8.50c. New York, while 7.75c. was asked for November and December delivery.

Other Metals.—Antimony continues downward and 11c. is quoted for Japanese and Chinese. Aluminium is quoted at 58c. to 60c. for No. 1 virgin metal. Platinum is quoted at \$60 per ounce; Magnesium at \$3.50 per pound; Quicksilver at \$75.00 per flask, with silver at 66¼c.

Coming Meetings and Events

American Institute of Metals and American Foundrymen's Association, Foundrymen's Convention, Cleveland, Sept. 11-16.

American Institute of Mining Engineers, Arizona, Sept. 18-23.

Mining and Metallurgical Society of America, New York Section, New York, Sept. 21.

Second National Exposition of Chemical Industries, New York, Sept. 25-30.

American Chemical Society, New York, Sept. 25-30.

American Electrochemical Society, New York, Sept. 28-30.

Technical Section, American Paper and Pulp Association, New York, Sept. 25-30.

American Institute of Chemical Engineers, New York, Jan. 10-13, 1917.

Technical Societies and the Second National Exposition of Chemical Industries

The society meetings and the Second National Exposition of Chemical Industries which are to be held in conjunction with each other in New York from Sept. 25 to 30, provide a week of great interest and value to the chemical industries and to all those interested in chemistry. It is a combination which no one so interested can afford to miss.

The American Electrochemical Society has planned a series of very interesting sessions for its thirtieth general meeting, which will be held during the week of the show on Sept. 28, 29 and 30. The meeting will be opened on Thursday with the "Made in America" technical session devoted to a review of American progress in the electrochemical industry. A complimentary smoker will be held on Thursday evening to which members of the American Chemical Society, and other visiting engineers are invited, and on Friday evening there will be a joint banquet at the Waldorf-Astoria of the members of the American Chemical Society, The American Electrochemical Society, and the Technical Association of the Pulp and Paper Industry. This will be a subscription banquet and the price of tickets to members will be \$3.50; additional tickets for guests will be obtainable at cost, or about \$7.

The first general session of the American Chemical Society will open at Columbia University on Tuesday morning, Sept. 26, and arrangements are being perfected for a public meeting in the large hall of the College of the City of New York on Tuesday afternoon, when addresses will be made of general public interest pertaining to the interesting developments in the field of applied chemistry during recent years. More detailed announcements will be given in a later issue.

Dr. Charles H. Herty, of the University of North Carolina, president of the American Chemical Society, will open the exposition on Monday, Sept. 25, at 2 o'clock in the afternoon, with an address reviewing the history of chemistry and the chemical industries in this country and outlining developments since the outbreak of war in Europe.

On Aug. 1, 1915, there were thirty-seven pledged exhibitors to the First National Exposition of Chemical Industries. On Sept. 20, 1915 the Exposition opened with eighty-three exhibitors.

On Aug. 1, 1916, there are 125 pledged exhibitors to the Second National Exposition of Chemical Industries—an increase of nearly 350 per cent. By Sept. 25 of this year the management expects to have the third floor of the Grand Central Palace filled. Out of the eighty-three exhibitors of last year all but four will exhibit again this year. Last year there were 63,377 admissions to the Exposition—this year it is not unreasonable to expect an attendance of 100,000.

Appliances and equipments used in the whole range of American chemical industry will be shown.

While it is utterly impossible to show large processes in actual operation yet the equipments used will be on exhibition and there will be men present, expert in their various lines to explain. One great section of the Exposition will be devoted to the paper industry. The dye-stuff industry will be extensively represented. There will be shown what has been accomplished in America in the production of potash. An interesting feature will be a demonstration of the ultra-microscope. The great natural resources of the United States and Canada will be vividly shown. Many chemical processes, that could not be demonstrated in actual operation in such a building as the Exposition will be shown in motion pictures.

The Working Efficiency of Rolling Steel

BY SIDNEY CORNELL

Descriptive matter in relation to the blast furnace, the open-hearth, and the rolling mill is abundant in technical magazines, but the human side of the art is rarely touched upon by any writer, either in America or in Europe. Technical men have given us many valuable articles from a purely scientific standpoint, and one author states that metallurgical progress in connection with the blast furnace has not been what it should have been, due to the fact that the authors of articles are inclined to write lop-sided heat balances rather than devote their time to mechanical problems.

This may be true, but all progress costs money, and the money seldom comes from the man who operates the various metallurgical apparatus, single units of which may cost as much as \$1,000,000 to build and \$2,500,000 per year to operate. Another and deeper side of the problem, therefore, presents itself, the basis of which is accounting.

The accounting of the steel works industry has not yet been approached in such a detailed way as to make it truly scientific, I may safely state that steel works accounting is usually a most lop-sided affair of lumped expenditure and lumped returns, yielding a fair profit or otherwise, but usually the former.

Efficiency involves detail, and the attendance to detail will reward its followers sooner or later. In this article I will present not a series of accounting methods, but a compilation of observations involving details, each detail in turn often involving further details, but leading up to the unknown quantity of what it really costs to make steel.

In many ways the steel industry practices material efficiency of a high order. Metal is produced in a fair degree of efficiency as far as yield is concerned and it is possible to follow the process visually in the transformation of iron ore to finished steel article. In this transformation the money expended can reach surprising figures, and the steel works early became efficient in the utilization of all scrap material. However, they have never known what the value of that scrap material was, and have apparently never cared. In the following I wish to present observations which will bring out in a simple manner the real cost of making steel.

My figures are taken from many sources, but I am confining the discussion to a steel plant containing blast furnaces, open-hearth furnaces, bloomers, billet mills, and merchant mills, and all of the auxiliaries needed in such a plant. Some of the cost units used would be higher and others would be lower for other localities, and for any specific case these changes would have to be duly considered, but the working of the method is plainly evident. A plant located some twelve miles from Pittsburgh is taken as representative.

The plant covers 150 acres of land, and includes six blast furnaces, thirty-two open-hearth furnaces, a 38-in. and a 40-in. blooming mill, a rail mill used to roll light shapes, billets, and sheet bar, and continuous mills, arranged so that the product of the 38-in. mill passes through the rail mill and continuous mill and so that the product of the 40-in. mill may be passed through another continuous mill. Secondary to these are five merchant bar mills, namely a 22-in., a 13-in., two 10-in. mills and an 8-in. mill. For convenience the above mills are here called 1A Bloomer (38 in.); 2A Bloomer (40 in.); 1B rail mill; 1C the one 14-in. continuous mill; 2B the other 14-in. continuous mill. The merchant mills are called 1M (10 in.), 2M (13-in.), 3M (8 in.), 4M (10 in.), and 5M (22 in.). The value of such a plant, bought

piecemeal, and involving great improvements from time to time with the writing off of values, makes the subject of overhead a difficult one and the only way to arrive at any figures worth considering is to give present working values comparatively.

The product of such a plant for an average month is tabulated in Table I.

TABLE I—DISTRIBUTION OF STEEL AND IRON IN THE VARIOUS DEPARTMENTS FOR AVERAGE MONTH

Part of Mill	TOTAL CHARGED		Product		SCRAP METALLURGICAL		Losses, Etc.	
	Am't Tons	Per Cent	Am't Tons	Per Cent	Am't Tons	Per Cent	Am't Tons	Per Cent
Blast furnaces	80,100	...	80,100	...				
Pig to O. H.	64,500	...	64,500	...				
Pig sold	15,600	...						
Open hearth	116,000	100	103,200	88.96	8,000	5.17	8,800	5.87
Castings	300	...	300	...				
Steel to mills	102,900	...	102,900	...				
1A Mill	66,000	100	56,800	86.06	8,000	12.12	1,200	1.82
1B Mill	56,800	100	54,000	95.07	2,500	4.40	300	.53
1C Mill	14,100	100	13,000	92.20	1,000	7.09	100	.71
2A Mill	36,900	100	29,200	79.13	7,100	19.24	600	1.62
2B Mill	10,500	100	9,700	92.38	750	7.14	50	.47
1 M. Mill, 10 in.	8,000	100	7,200	90.00	650	8.12	150	1.88
2 M. Mill, 13-in.	9,000	100	8,000	88.88	900	10.00	100	1.12
3 M. Mill, 8-in.	1,550	100	1,400	90.32	125	8.06	25	1.62
4 M. Mill, 10-in.	2,800	100	2,500	89.28	250	8.93	50	1.79
5 M. Mill, 22-in.	8,500	100	7,400	87.06	1,000	11.76	100	1.18
Special product of Merchant Mill	2,200	100	2,150	97.72	50	2.27		

The material efficiency of the various mills is shown in the column per cent under product. The net efficiency from a material standpoint is derived as follows:

The 102,900 tons of steel delivered to the mills are first rolled in mills 1A and 2A. Sixty-six thousand tons rolled in 1A, give 56,800 tons of product, which is rerolled in 1B mill, yielding in turn 54,000 tons of product, and from this 14,100 tons are rolled in 1C mill, giving 13,000 tons of product, so that out of the 66,000 tons rolled on in 1A mill, the product is $39,900 + 13,000 = 52,900$ tons.

The 2A mill rolls on 36,900 tons giving 29,200 tons from which 10,500 tons are rolled on in 2B mill, so that the net product from this side is $18,700 + 9,700 = 28,400$ tons.

The total product of mills 1A and 2A is thus $52,900 + 28,400 = 81,300$ tons, in the form of blooms, billets, sheet bar and light shapes. From these 81,300 tons there must be taken 29,850 tons of blooms and billets for mills 1M to 5M, leaving 51,450 tons for sale. These 29,850 tons give 26,500 tons of product. From this product 2200 tons are used to furnish 2150 tons of finished specialty, while the remaining 24,300 tons are saleable in the form of merchant bar.

The saleable product of the above steel plant is thus:

	Tons
Pig iron	15,600
Blooms, billets, sheet bar	51,450
Merchant bar	24,300
Special merchant bar product	2,150
Castings	300

or 15,600 tons of pig iron, and 78,200 tons of finished and semi-finished steel. As 116,000 tons of metal were charged to the open hearth and 78,200 tons of product were finally obtained, the material efficiency of the conversion is 67.4 per cent. During this conversion a total of 28,325 tons of metallic scrap is produced, together with 9475 tons of roll scale, cinder, etc., all of which must be remelted in the open hearth or blast furnace. It is quite obvious that the cost of this scrap and scale is not what the market value would be, and it is upon this point that the following tabulations rest.

In order to arrive at a basis for figuring the real

efficiency of a steel plant it is first necessary to consider all of the non-producing departments connected therewith and accordingly I am tabulating these departments as follows, using a decimal system of numbering.

The non-producing departments are a matter of simple accounting and each producing department bears the burden in exact proportion to the service rendered.

Account 1—Steam.	
“ 2—Water.	
“ 3—Electrical.	
“ 4—Transportation.	
“ 5—Maintenance shops.	
“ 6—Roll shop.	
“ 7—Laboratory.	
“ 8—Store rooms.	
“ 9—General works.	

The last item General Works is the only one that serves generally and the sum so expended must be distributed in proportion to the tonnage of the various producing departments.

The above nine accounts are dealt with in Tables II to X.

The average conditions for the production and utilization of steam for an average month's account is as follows, steam costing \$2.60 per boiler horsepower, month.

TABLE II—STEAM. ACCOUNT 1

Part of Mill	B.H.P.	Cost
Blast furnaces, steam consumed.	8,000	\$20,400.00
Steam sent to steel works from B. F.	9,100	
Steam generated in steel works.	4,670	
Total steam used in upper works.	13,770	35,800.00
Water, Steam used.	660	1,720.00
Electrical power.	2,175	5,650.00
Open hearth.	685	1,775.00
1A mill.	2,500	6,500.00
1B mill.	3,450	8,970.00
1C mill.	1,400	3,640.00
2A mill.	2,600	6,760.00
2B mill.	300	780.00
Total.	13,770	\$35,800.00
1M mill.	745	1,940.00
2M mill.	600	1,560.00
3M mill.	385	1,000.00
4M mill.	415	1,080.00
5M mill.	1,475	3,840.00
Special product.	100	260.00
Total.	3,720	\$9,880.00
Boiler horsepower. Coal fired.	8,390	
Boiler horsepower. Gas fired.	17,100	
Total	25,490	
Coal used = 10,500 tons		
Water used = 64,100,000 gallons		

Average conditions for water for average month with distribution in 1000 gal., and at a cost of \$0.004 per 1000 gal. pumped is given in Table III. Water for boilers excluded as cost appears in steam.

TABLE III—WATER. ACCOUNT 2

	1,000 Gallons	Cost
Blast furnaces	1,280,000	\$5,120.00
Open hearth.	175,000	700.00
1A mill.	30,000	120.00
1B mill.	50,000	200.00
1C mill.	25,000	100.00

From Table I we have the following scrap materials that must be disposed of and utilized as far as possible in the plant.

Metallic scrap ingot butts, etc., from open-hearth	6,000 tons
Bloom crops, and crop ends from bars, and rejected materials from the rolling mills (clean scrap)	22,325 tons
Metal loss in slags made in open-hearth	6,800 tons
Metal loss in roll scale, heating-furnace cinder in the rolling mills	2,675 tons

All of the above is not usable, due to contamination with dirty materials, brick bats, etc., but all of the clean scrap is directly usable in the open-hearth, and its recovery may be taken at 100 per cent.

In the case of open-hearth slags, they are not used in the blast furnace as ore, but are employed as a cleaning agent, to add manganese, etc., and their metallic content is thereby recovered.

Cinder and scale are used in the open-hearth replacing ore in the working of the heat, but this use is restricted to the getting of clean materials free from acid content.

In the following I have noted a reuse of 2000 tons of roll scale in the blast furnaces, and of 510 tons of roll scale in the open-hearth division, a total of 2510 tons,

having an average metallic content of 65 per cent iron. This gives a net recovery of 1631 tons of metal out of 2675 tons recorded loss, so that the material efficiency is 60 per cent.

In the recovery of metal from the slags produced in the open-hearth (where 6800 tons are so lost per month in the making of approximately 14,600 tons of open-hearth slag) only selected slag would be recharged in the blast furnaces, and the metal content of such slag would not average over 16 per cent. As 7200 tons of such slag was observed to be recharged, having a metal content of 1150 tons, and as 6800 tons were lost in the open-hearth slags, the material efficiency is about 17 per cent.

In order to arrive at the value of recovery of the waste materials, the following must be considered. The starting point is the blast furnace.

BLAST FURNACES

The value of the raw materials used in the blast furnaces, carries us back still further, to the materials in the ground. To determine the value at the furnace the calculations of Table XI are made.

TABLE XI—NET COST OF RAW MATERIALS AT FURNACE

	Per Ton
Value of the ore in the ground unmined	\$1.300
Average cost of stripping, loading and mining	.350
Transportation to lake ports, 60 miles at \$.005 per ton-mile	.300
Lake transportation, including interest	.260
Loading and unloading steamers	.050
Transportation from lower lake ports to Pittsburgh, 120 miles at 0.005 per ton-mile	.040
Unloading and transferring to stock pile at furnace	.040
Net cost of ore on stock pile	\$2.800
	Per Ton
Value of coking coal in the ground	\$0.60
Average cost of mining, etc.	.19
Beehive coke-oven yield = 66 per cent, or coal cost per ton coke is $(.60 + .19) \div .66$	\$1.197
Cost of coking above cost of coal	.813
Transportation from coke ovens to Pittsburgh	.710
Net cost of coke at furnace plant	\$2.72
	Per Ton
Value of limestone (blast-furnace grade) in the ground	\$0.400
Average cost of mining and loading	.230
Transportation from quarry to Pittsburgh, 100 miles	.500
Net cost of limestone at furnace plant	\$1.030

In as much as the various materials used in the blast furnace, open-hearth, or rolling mills are all converted into materials of value or wastes, the value of flue dust, open-hearth slags, and cinder and scale are unknown at this point. A = real value of flue dust considered as a product, that is its value if iron, flue dust and slag were considered the products of a furnace, the gases being utilized entirely at the furnace plant in the production of steam.

C = real value of open-hearth slag when ingot steel, metallic scrap and all slag are considered as products.

B = real value of roll scale when considered as the product of all rollings together with the finished product.

Using these unknown values we give in Table XII the cost of iron per ton.

TABLE XII—BLAST FURNACES

Material	Tons per Month	Cost per Ton	Material Cost per Month	Cost per Ton, 1500
1 Lake-ores	156,700	\$2.80	\$436,800.00	\$2.82
2 Flue-dust, recharged	3,600	A	3,600 00xA	0.0000A
3 Roll-scale	2,000	B	2,000 00xB	0.0000B
4 Open hearth slags	7,200	C	7,200 00xC	0.0000C
5 Coke	83,000	2.72	225,760.00	2.818
6 Limestone	36,000	1.03	37,080.00	0.463
Products				
1 Pig iron	80,100			
2 Flue dust	8,200			
3 Slag	18,700			

It is obvious that although the flue dust produced was charged for once as ore, that it is an accumulative material, and therefore its value of \$2.80 as ore should be deducted, the cost of flue dust recharged is the cost to make iron + flue dust + slags less \$2.80 per ton. Herein may enter a doubtful economy. In connection with flue dust it may be noted that from the 8200 tons produced there are recharged 3600 tons. This gives a material efficiency of 43 per cent for flue dust.

Writing in form of an equation the cost of materials per ton of iron, we get: Cost material per ton iron = $\$8.733 + 0.045A + 0.025B + 0.090C$. But to arrive at the total cost the cost above the materials must be considered. This averages as stated in Table XIII.

In order to arrive at the net cost above the materials, it is necessary to consider all credits, the laying aside of a fund for relining, and other contingent fund. A blast furnace will last approximately six years on one lining, requiring nearly \$150,000 to completely repair a furnace after making 1,000,000 tons of iron, and 15 cents a ton is taken as representative of a relining contingency and 3 cents a ton as representing general contingency.

TABLE XIII—COST ABOVE MATERIALS. BLAST FURNACE

Item	Cost Average Month	Per Ton Iron
1 Superintendents, clerks, etc.	\$2,330.00	\$0.0291
2 Ore bridges and ore pile	2,225.00	0.0277
3 Stocking and charging	9,000.00	0.1123
4 Blowing	14,000.00	0.1748
5 Hot blast	3,900.00	0.0487
6 Casting	3,500.00	0.0437
7 Material used in repairs	7,500.00	0.0936
8 Refractories used in repairs	3,800.00	0.0474
Total	\$46,255.00	\$0.5773
1 Steam. Boiler horsepower used	\$20,400.00	\$0.2547
2 Water	5,120.00	0.0639
3 Electricity	1,750.00	0.0218
4 Transportation	10,000.00	0.1248
5 Shops. Labor used for repairs	14,115.00	0.1762
6 Laboratory	2,000.00	0.0249
7 Tools and supplies	1,725.00	0.0215
8 General works	8,300.00	0.1036
Grand total	\$109,665.00	\$1.3687
1 Relining contingency	12,000.00	0.1500
2 General contingency fund	2,400.00	0.0300
Total	\$124,065.00	\$1.5487
Credit for steam sold	23,660.00	0.2954
Net cost above materials	\$100,405.00	\$1.2533

The products of value from the blast furnace are iron and flue dust. The latter is of value only when used as ore, and it will be noted from the tables that flue dust is produced at the rate of 8200 tons per month and reused at the rate of 3600 tons, so that this material is accumulative. There are produced in an average month 80,100 tons of iron, and of iron and flue dust and slags 136,400 tons.

Thus we have the total cost of iron per ton

$$= \$8.733 + 0.045A + 0.025B + 0.090C + \$1.2533$$

$$\text{or} = \$9.9863 + 0.045A + 0.025B + 0.090C$$

As there were made 80,100 tons of iron and a total of 136,400 tons of iron, flue dust and slags, which may be considered equally as products, and as $80,100 \div 136,400 = 0.59$, the value of flue dust would be $0.59 \times$ cost of iron — \$2.80 per ton.

$$\text{Hence } A = 0.59 \times (9.9863 + 0.045A + 0.025B + 0.090C) - \$2.80 \text{ per ton.}$$

$$A = \$5.99 + 0.027A + 0.015B + 0.054C = \$2.80,$$

or

$$0.973A = \$3.191 + 0.015B + 0.054C, \text{ hence}$$

$$A = \$3.27 + 0.0154B + 0.055C.$$

$$\text{Thus the cost of iron} = \$9.9863 + 0.045 \times (3.27 +$$

$0.0154B + 0.055C) + 0.025B + 0.090C$. If E = cost of iron per ton, we have

$$E = \$9.9863 + 0.147 + 0.0257B + 0.0925C.$$

B and C cannot be eliminated until more values are determined, so this brings us to the discussion of the open hearth.

From Table I we have the following figures:

Material charged to open hearth, metallic	116,000 tons
Product from the open hearth	103,200 tons
Metallic scrap, i.e. pit and skull scrap, ingot butts, etc.	6,000 tons
Loss, metallic, i.e. metallic content of slags, etc.	8,800 tons

The distribution and values of the materials going into the above are given in Table XIV.

TABLE XIV

Material	Tons per Month	Base Cost per Ton	Cost per Month	Cost per Ton Steel
Hot metal	56,900	E	\$56,900.00E	\$0.551 E
Moulds and stools	1,920	\$25.00	48,000.00	0.4650
Iron scrap	760	20.00	15,200.00	0.1470
Home steel scrap	28,325	D	28,325.00D	0.274 D
Heavy bought scrap	2,335	13.00	32,955.00	0.3194

Dolomite	3,170	2.90	9,193.00	0.0891
Limestone	7,100	1.05	7,455.00	0.0722
Lump ore	2,850	4.50	12,825.00	0.1242
Fluorspar	125	1.80	225.00	0.0022
Hot metal	9,260	E	9,260.00E	0.0807E
Ferromanganese	400	80.00	32,000.00	0.3100
Ferrosilicon	30	40.00	1,200.00	0.0116
Sulphur	10	35.00	350.00	0.0034
Coal. Dry powdered	200	2.00	200.00	0.0019
Aluminium	12	336.00	4,032.00	0.0391
Magnesite	140	25.00	3,500.00	0.0339
Chrome ore	55	16.00	960.00	0.0096
Clay	260	1.35	351.00	0.0034
Loam	450	1.10	495.00	0.0048
Coke	725	2.72	1,972.00	0.0191
Producer gas (coal)	23,920	1.88	44,969.00	0.4357

$$\text{Total} = \$290,680 + 66,160E + 28,325D + 510B.$$

The value of all steel scrap in the plant is signified by D at this point.

The products obtained from the material of Table XIV are:

Ingot and castings	103,200 tons
Ingot butts	1,700 tons
Pit scrap, etc.	4,300 tons
Run-off slag	3,100 tons
Ladle slag	4,100 tons
Normal slag	7,300 tons
Total slags	14,700 tons
Metallic scrap	6,000 tons

Thus the divisor for value of open-hearth slag is 123,900. In order to determine the cost of steel, the cost above materials is figured as given in Table XIVa.

TABLE XIVa—COST ABOVE MATERIALS—OPEN HEARTH

Account	Cost per Month	Per Ton (103,200 Tons)	Per Ton (123,900 Tons)
1 Steam	\$1,775.00	\$0.0172	\$0.0143
2 Water	700.00	0.0068	0.0056
3 Electricity	1,375.00	0.0133	0.0111
4 Transportation	5,000.00	0.0485	0.0401
5 Slags	9,285.00	0.0900	0.0750
6 Laboratory	1,400.00	0.0135	0.0113
7 Material in maintenance	2,500.00	0.0242	0.0202
8 General works	10,260.00	0.0995	0.0829
1 Refractories	2,700.00	0.0261	0.0218
2 Rebuilding	14,450.00	0.1401	0.1168
3 Store supplies	2,500.00	0.0242	0.0202
4 Contingent fund	3,190.00	0.0309	0.0258
1 Superintendents, clerks	2,900.00	0.0281	0.0234
2 Stocking and charging, boxes	11,350.00	0.1101	0.0917
3 Charging furnaces, rollers, etc	4,350.00	0.0422	0.0351
4 Melting and gas tending	17,550.00	0.1702	0.1419
5 Ladle lining	4,400.00	0.0420	0.0356
6 Calcining and alloy house	1,850.00	0.0179	0.0141
7 Mould handling	7,750.00	0.0751	0.0626
8 Scrap and cinder drop or skullcracker	7,000.00	0.0679	0.0565
9 Inspection, shipping and stripping	15,500.00	0.1503	0.1253
Total	\$127,785.00	\$1.2387	\$1.0319

Thus the cost of steel per ton in dollars = $2.8162 + 0.641E + 0.274D + 0.005B + 1.2387$. The cost of open-hearth slag = $2.346 + 0.533E + 0.228D + 0.0041B + 1.0319$.

But E = value found under blast furnaces; hence,

$$C = 3.378 + 0.533 \times (10.133 + 0.0257B$$

$$+ 0.0925C) + 0.228D + 0.0041B,$$

$$C = 3.378 + 5.40 + 0.014B + 0.049C + 0.228D + 0.004B,$$

$$0.951C = 8.778 + 0.018B + 0.228D,$$

$$C = 9.24 + 0.019B + 0.24D$$

= value of open-hearth steel, slag and scrap.

It will be noted in Table I that open-hearth steel is used in the blast furnaces to the extent of 7200 tons per month, and produced at the rate of 14,700 tons per month (a material efficiency of 49 per cent), so that 7500 tons of open-hearth slag have no value. Allowing the open hearth due credit for the slag used in the blast furnaces, the cost of open-hearth steel is: $290,680 + 66,160E + 28,325D + 510B + 127,785 - 7200C$, or the cost per ton of open-hearth steel, which we will call F at this point, is:

$$F = \$4.055 + 0.641E + 0.274D + 0.0050B - 0.069C.$$

In order to arrive at the value of the scrap and scale from the mills, the accounts are tabulated in Tables XV and XVI.

TABLE XV—MILL ACCOUNT

	1A	1B	1C	2A	2B
1 Steam	\$6,500.00	\$8,970.00	\$3,640.00	\$6,760.00	\$780.00
2 Water	150.00	200.00	100.00	180.00	100.00

2 Fuel	965.00	1,000.00	185.00	335.00	1,125.00	
Total	\$15,995.00	\$16,275.00	\$9,015.00	\$10,595.00	\$19,800.00	\$2,270.00
Rollled on (Tons)	8,000	9,000	1,550	2,800	8,500	2,200
Scrap	650	900	125	250	1,000	50
Scale	150	100	25	50	100	
Product	7,200	8,000	1,400	2,500	7,400	2,150
Cost per ton product	\$2.207	\$2.034	\$6.439	\$4.238	\$2.675	\$1.056
Cost per ton product, scrap and scale	\$1.987	\$1.808	\$5.816	\$3.784	\$2.212	\$1.031

At this point it is necessary to follow the steel through its various rerollings.

The steel rolled in 1A Mill is rerolled in 1B Mill, and part of the product is then rerolled in 1C Mill. Product from 1B Mill is rerolled in 1M Mill and 2M Mill, and part of the product from 1C Mill is rerolled in 3M Mill and 4M Mill. Part of the product from 2A Mill is rerolled in 2B and part in 5M Mill. The special prod-

ucts are assumed to take their raw material from 2M Mill. Accordingly the values are tabulated in Table XVI, the scrap being figured direct, and remelted in the open hearth, and its value D being directly determined. In the case of roll scale, a metallic content of 65 per cent average is taken, the figures tabulated, being, however, metallic contents and not figured as the oxide.

TABLE XVII—VALUES OF SCRAP AND SCALE

Part of Mill	Scrap, Tons	Roll Scale	Value per Ton	Total Cost
Openhearth	6,000		$\$9.24 + 0.019B + 0.24D$	$1440D + 114B + \$55,425.00$
1A mill	8,000	1,200	$F + 0.439$	$9200F + 1,080D$
1B mill	2,500	300	$F + 0.439 + 0.586$	$2500F + 2,870.00$
1C mill	1,000	100	$F + 0.439 + 0.586 + 0.947$	$1100F + 2,189.00$
2A mill	7,100	600	$F + 0.739$	$7700F + 5,691.00$
2B mill	750	50	$F + 0.739 + 0.728$	$800F + 1,173.50$
1M mill	650	50	$F + 0.439 + 0.586 + 1.987$	$800F + 2,409.50$
2M mill	900	100	$F + 0.439 + 0.586 + 1.808$	$1000F + 2,833.00$
3M mill	125	25	$F + 0.439 + 0.586 + 0.947 + 5.816$	$150F + 1,192.50$
4M mill	250	50	$F + 0.439 + 0.586 + 0.947 + 3.784$	$300F + 1,726.70$
5M mill	1,000	100	$F + 0.739 + 2.212$	$1100F + 3,246.00$
Special product	50		$F + 0.439 + 0.586 + 1.808 + 1.031$	$50F + 193.50$
Total	28,325	2,675		$25,000F + 1,440D + 114B + \$2,915.50$

Table XVII gives the values of scrap and scale and from it we get

$$31,000D = 25,000F + 1,440D + 114B + 82,943.50$$

$$D = 2.676 + 0.806F + 0.046D + 0.0037B$$

$$D = 2.812 + 0.847F \text{ (since } B = 0.65D)$$

We are now able to give Table XVIII, which gives representative real costs as they would be in the steel plant.

It will be seen from Table XVIII that flue dust costs really \$4.146 to make and many plants are spending one more dollar per ton to sinter this material, which brings the cost up to \$5.146 per ton. This material is expected to replace ore at \$2.80 a ton. It is quite apparent that this is doubtful economy.

TABLE XVIII—PRIME COST OF MATERIALS DETERMINED FROM THE FOREGOING

Material	Cost per Ton	Equation	Prime Cost
Flue dust	A	$3.27 + 0.0154B + 0.055C$	\$4.146
Pig iron	B	$10.133 + 0.0237B + 0.0925C$	12.013
Open hearth slag	C	$2.346 + 0.533E + 0.228D + 0.0041B$	14.841
Open hearth steel	F	$4.055 + 0.641E + 0.274D + 0.005B - 0.069C$	15.371
Average steel scrap	D	$2.812 + 0.847F$	9.991
Average roll scale	B	$0.65D$	4.083

TIME STUDY FOR VARIOUS WORKING UNITS

A blast furnace has a life of approximately 1,000,000 tons on one lining, and accordingly is idle at the end of a period of six years. In order to completely repair a furnace after such a run, a period of approximately four and one-half months is required. Thus the time lost for rebuilding purposes is 5.88 per cent of the total time from blowing-in to blowing-in. In a plant involving six furnaces there would be lost a total of twenty-seven furnace-months for the relining in a period of six years so that this non-productive period is of material consideration, or 6.2 per cent of the working time.

An open-hearth furnace has a working period of approximately 400 heats, and approximately one month's time is consumed each year for rebuilding, so that this rebuilding period represents 8.5 per cent of the time from run to run, although including the time required for replacement of one roof.

The rolling mills are all subject to mechanical repairs, not being affected chemically as the blast and open-hearth furnaces. The heating furnaces in conjunction with a rolling mill are subject to the wearing out due to chemical changes, and the pit furnaces as operated, representing eleven units, are subject to one

pit down for repairs continually, leaving ten in operating conditions, so that to these heating furnaces 9 per cent of the time is consumed in rebuilding.

In connection with all of the units unavoidable delays are present, such as tapping time, *i.e.*, when the furnace is not being used due to blast off, mechanical delays affecting all units, roll change time during the time when mill should be working, etc., all of which should be subject to investigation. In Table XIX there is also included the operation period of a thirty-day month, wherein the blast furnaces are in continuous operation, the other units being allowed four Sundays or the equivalent off per month.

TABLE XIX—PERIOD OF 30-DAY MONTH

Unit	Number	Rebuilding, per Cent	Perfect Time per Unit, Hours	Perfect Time Gross, Hours	Unavoidable Delays, Hours
Blast furnaces	6	6.2	720	4,320	72
Open hearth	32	8.5	624	19,968	192
Strippers	2		624	1,248	
Soaking pits	11	9.0	624	6,864	
1A mill	1		624	624	26
1B mill	1		624	624	78
1C mill	1		624	624	13
2A mill	1		624	624	54
2B mill	1		624	624	13
1M mill	1		624	624	67
2M mill	1		624	624	91
3M mill	1		624	624	39
4M mill	1		624	624	67
5M mill	1		624	624	104

The following time studies are averages of observed conditions and are representative:

TIME STUDY FOR BLAST FURNACES

Number of Units	Operation	Lost Time Rebuilding, per Cent	Lost Time Unavoidable, per Cent	Working Efficiency, per Cent
6	Continuous	6.2	1.66	92.14

TIME STUDY FOR OPEN HEARTH

As noted in Table XIX, the lost time due to rebuilding is 8.5 per cent of the working time, so that out of a plant of thirty-two furnaces there are twenty-nine furnaces in continuous operation, giving some 7950 ingots a week, and making some 317 heats of twenty-five ingots each. The figures in time are in parts of an hour.

TABLE XX

	Per Month	Per Cent	Hours per Heat
Units	32	100.0	
Off-rebuilding	3	8.5	
Operating	29	91.5	
Hours	1,373		
Continuous—32 units	19,968		
Actual—29 units	18,080	100.00	
Rebuilding	1,888		
Unavoidable delays	192	1.06	
Net working time for 29 units	17,888	98.94	
Charging	3,199		2.33
Melting	9,721		7.08
Tapping	341		.25
Capacity	343		.25

Total capacity is 13,697 hours

Total of operations of 29 units per month	48,080 hours	Per Cent
Total lost and chargeable to operation	192 hours	1.06
Actual time consumed in the blast furnaces	47,888 hours	75.26
From the average efficiency of the open-hearth as run—29 units	75.00	
At the average efficiency of the plant—32 furnaces	68.00	

STRIPPERS

The plant contained two strippers, and the following are noted performance:

	Per Month Hours	Per Heat Hours	Per Cent.
Transfer from poring stand to strippers	220	0.16	
Stripping	563	0.41	
Heats stripped	1373	1	
Hours in month	624		

Number of heats stripped if the operation were continuous = 1522 by one machine, or 3044 for the pair of strippers.
Working efficiency of two strippers = $1373 \div 3044 = 45.1$ per cent.

SOAKING PITS

A soaking pit of four holes will hold approximately one heat of twenty-five ingots, and out of a plant of eleven pits, one set will be off for rebuilding, so that ten pits are in continuous operation.

	Per Heat, Hours
Second transfer from the strippers to pits	0.08
Charging in Pits	0.39
Soaking	1.02
Drawing pits	0.42
Bottom making	0.20

Total time cycle from full to empty pits, excluding the transfer, is approximately two hours per heat.

Thus one set of pits will accommodate twelve heats per day in continuous operation. And ten sets of pits will accommodate 120 heats per day.

The actual average performance of ten pits for the ingots from the twenty-nine open-hearth furnaces as operated was at the noted tabulated rate of fifty-three heats per day of 24 hours.

Working efficiency = $\frac{\text{Actual accommodation}}{\text{Maximum capacity}} = \frac{53}{120} = 44\%$

ROLLING MILLS

The following are average results such as may be expected from the usual rolling mill plant:

	Per Heat, Hour	Tons Rolled per Hour
Transfer from the pits to the rolling mill table	0.20	
Rolling in 1A mill to bloom	0.48	1.52
In bloom shears, cropping and making 2 blooms	0.28	

The average heat is taken as 73 tons and of 25 ingots per heat, and as the slowest operation is the tonnage determining, the capacity is the time of this operation in hours divided into the tonnage for that time.

From Table XIX it will be noted that such a mill operating for one month has 26 hours down due to unavoidable delays, such as roll change, mechanical breakdown, etc., coming at extraordinary time, which leaves 598 hours for working, out of a possible 624 for perfect time. Ordinarily roll changes on such a mill should take place on the Sunday time.

Thus the actual working hours—598 times 152 tons = 90,000 tons—is the maximum capacity for continuous operation.

The actual average tonnage of such a mill is noted as 66,000 tons.

Thus the working efficiency of 1A Mill = 73%.

1B MILL

The two blooms from 1A Mill delivered to the rougher of 1B Mill are rolled simultaneously, delivered to 1 Stand, where one is rolled into billet form and one into the rough billet for shape. Thus 1 Stand has the same capacity as the rougher. On account of the lengthening out of the rolled material from pass to pass, the capacity of such a mill is limited to the time of the longest pass.

From 1 Stand there would be delivered one billet finished to 4" x 4" section, and the rough shaped for

the other stands of 1B Mill. The 4x4 section can either become commercial billets being sheared to salable length, or the raw material for 1C Mill. Thus the following time study comes in:

TABLE XXI

Part	Time in Hours per Heat of 73 Tons, 25 Ingots	Tons Rolled On per Hour (By Consuming Operation)
Two blooms in rougher.		
Rougher	0.47	
1 stand	0.50	146
	(2 pieces)	
2 pass	0.125	
3 pass	0.175	
4 pass	0.250	
5 pass	0.400	
6 pass	0.550	132
Billet shears for part product No.		
1 stand	0.825	88
1C mill, complete	0.825	88
Sawing product from No. 6 pass	0.250	

TIME STUDY OF 1B AND C MILLS

Since all of the product passes through the rougher and 1 Stand it is evident that there must be an alteration between the 4x4 shears and the 1C Mill, for maximum production, of all three considerations, so that one billet would go into 4x4 while rolling for the 1B Mill, and the next following billet go to the 1C Mill.

From the above it follows that as there are 624 possible hours in a month, and from Table XIX 78 hours are deducted for unavoidable delays, the remaining 546 are tonnage rolling hours, which at 132 tons per hour for the 1B Mill slowest pass gives 72,072 tons as the maximum capacity.

Thus capacity = 72,000 tons, while the actual performance is 56,800 tons, hence working efficiency of 1B Mill = 78%.

1C Mill, working 624 less 13 hours for unavoidable delay, gives 611 tonnage rolling time, which at 88 tons per hour is 53,768 tons per month.

The actual material rolled on for such a mill averages 14,100 tons, so that the working efficiency of such a mill is 26%.

As worked alternately giving product to the 1C Mill, the 1B Mill capacity is limited to the time of pass 1 only, which rolls two blooms down at the same time, having a capacity of 146 tons per hour. With tonnage rolling time of 546 hours, this capacity is 79,716 tons per month.

Thus the working efficiency at maximum capacity = 73%.

TIME STUDY FOR 2A AND B MILLS

The performance of 2A Mill will be different from 1A Mill on account of the different product desired, involving greater reduction by the mill from ingot to finished bloom or slab. The following table is representative of time consumed in the operations. Time in hours:

	Per Heat	Tons Rolled on per Hour
Transfer of ingot from soaking pits to rolling mill table	0.200	80
Rolling in 2A mill to bloom or slab	0.910	
Transfer to shears	0.625	
Shearing, average	0.750	

The working time of 2A Mill averaged as follows:

	Hours
Total available hours per month	624
Unavoidable delays	54
Net rolling time	570

570 hours' rolling time at 80 tons per hour, for the time-consuming operation in the rolling mill, is 45,600 tons per month.

The average performance of the mill is 36,900 tons rolled on per month.

Hence the working efficiency of 2A Mill = $36,900 \div 45,600 = 80\%$.

Part of the product of 2A Mill is rerolled in 2B Mill into small billets.

	Per Heat	Time per Hour
Transfer from rolling mill to 1 stand of 2B mill	0.650	
Time to roll in 2B mill, rolling on a bloom sheared into two pieces	1.000	7
Transfer from 2B mill to hot beds	0.400	

The time-consuming operation rolled at the rate of 73 tons per hour, and the total available rolling time for such a mill is 624 hours, less 13 hours for roll change, repairs of mechanical defects, etc., giving a net rolling time of 611 hours. Thus the maximum capacity of such a mill is 44,600 tons per month.

The actual performance for the mill averages 10,500 tons rolled on per month.

Hence the working efficiency is $\frac{10,500}{44,600} = 23.5\%$.

All of the products of the above mills are allowed to cool, and then transported to the merchant mills. The heat lost would be valuable if the products could be utilized at once in the bar mill furnaces, and proper placement of such mills could utilize such heat efficiently.

TIME STUDY OF MILLS, 1M TO 5M

Table XXII gives the working efficiency of the bar mills.

The time consuming pass or operation is taken as guide to maximum capacity.

TABLE XXII—TIME STUDY OF THE BAR MILLS

Mills	1M Mill	2M Mill	3M Mill	4M Mill	5M Mill
Heating furnaces, minutes	40	40	30	40	40
Time determining pass, in seconds	35	80	36	80	45
Average weight of billet, lb.	300	1,200	80	220	800
Capacity of slowest pass in tons per hour	16.6	22.7	3.57	5.8	28.6
Time for 1 ton, hours	0.60	0.11	0.280	0.171	0.035
Total hours in month	624	624	624	624	624
Unavoidable delay	66	91	39	97	194
Net rolling time	558	533	585	527	430
Maximum tonnage per month	9,230	12,100	2,088	3,230	14,800
Average actual tonnage per month	8,000	9,000	1,550	2,800	8,000
Working efficiency	86%	74%	74%	86%	57%

The diversity of product rolled on such mills naturally retards the product and the obtaining of maximum capacity of material rolled on. A gage to this diversity would be the amount of roll change that such mills are subject to.

In order to appreciate what the attainment of more perfect working efficiency would mean, the two tables, XXIII and XXIV, attached for a summary of the foregoing, should be given due consideration.

These figures of Tables XXIII and XXIV give an idea as to what betterment of mechanical working and organization would do toward economy in the rolling mill.

The valuations of product are not market values, as the cost figures are not those of product but of the amount of material handled, rolled on, etc., and thus are prime costs representing the handling of all ma-

TABLE XXIII—SUMMARY

Part of Plant	Working Efficiency	Prime Cost per Ton Rolled On	Tons Material per Month	Cost of Handling	Cost as it at 100 Per Cent Efficiency	Difference
Blast furnaces	92.14	\$12,019	80,100	\$962,200.00	\$1,044,000.00	\$181,800.00

terials. Any betterment would naturally increase the profit, due to greater credits and less net cost of the products salable. Some of the figures for single departments warrant the so-called research action, but the problems are more of a kind to be solved by a planning department than by chemical or mechanical experts. In spite of the relatively great material efficiency of the average steel plant, the fact that much time is lost and the working efficiency of some departments is low, makes the problem one for a staff of men, and not the work of the single manager or man directly in charge of a single producing unit. Each and every department's close co-operation is essential for the approach to 100 per cent working efficiency. This calls for planning, routing and grouping of work, even though the materials handled run into the thousands of tons daily.

In all of the above calculations it will be noted that the figures for mill rolling performance relate to the material rolled on and not the product obtained. This method gives a definite means of obtaining capacity, while it would not be so if the product obtainable from such mills were taken as the basis. Product in turn will be determined by the quality of the material rolled on, the skill of the operatives, etc.

It is the practice in rolling steel to compensate many employees by piece work or tonnage production, but in order to obtain maximum production it is quite obvious that the working efficiency is a figure of great importance, and this should not be kept hidden. With scarcity of labor becoming a paramount factor in all industries, the working efficiency of all mechanical appliances, from machine tools to blast furnaces, is something to be reckoned with; and it seems that there is a profitable field of endeavor in the steel industry for the planning room and for planning systems such as practised in the production of mechanical and electrical finished products, taking this function away from the man-driving managers so often in steel plants.

The Taylor Instrument Companies, Rochester, N. Y., are building a new up-to-date power plant containing automatic stokers, electric coal and ash handling equipment; coal, water and steam weighing and measuring instruments.

Large Increase in By-Products from Coke Ovens

Statistics as to the recovery of by-products from coke ovens in the United States in 1915, contained in a report recently issued by the Geological Survey show the tremendous growth of the by-product coke industry up to the end of 1915. The value of the by-products in 1915 was nearly \$80,000,000 as compared with a previous high value of \$17,500,000 in 1914. The greatest increase was in benzol products whose value rose from less than \$1,000,000 in 1914 to more than \$7,760,000 in 1915. Benzol has been recovered in this country from coke-oven gas for a number of years but prior to 1915 the market was small and the price low. The following table shows the amounts and value of the various products recovered. The increase in by-product coking has been very great since the beginning of this year and production is far in excess of the 1915 figures.

BY-PRODUCTS OBTAINED FROM COKE-OVEN OPERATIONS IN 1915

Product	Quantity	Value	Average Value
Tar obtained and sold, gallons	138,414,601	\$3,568,384	\$0.026
Ammonia obtained and sold	199,900,487	5,648,958	.028
Sulphate, pounds	10,626,612	1,240,473	.117
Liquor, gallons	30,002,196	2,978,044	.099
Anhydrous, pounds	23,667,614		
Gas produced, M cubic feet	17,196,426	3,083,311	.179
Surplus gas sold or used	27,590,624	3,158,129	.114
Illuminating, M cubic feet	39,568,864	2,383,459	.060
Domestic fuel, M cubic feet

Benzol products:			
Crude light oils, gallons	13,082,678	4,304,281	.33
Secondary light oils, gallons	182,039	28,731	.16
Benzol, gallons	2,616,483	1,428,323	.568
Toluol, gallons	623,506	1,529,803	2.46
Solvent naphtha, gallons	196,151	46,233	.24
Naphthaline, pounds	465,866	46,959	.10
Other products		379,491	
Coke, short tons	14,072,895	\$29,824,579	
		48,568,325	3.45
		\$78,382,904	

* Includes breeze, retort carbon, domestic coke and coke dust, and aniline oil.

These by-products were obtained by the carbonization of 19,500,000 tons of coal, from which 14,000,000 tons of coke was obtained.

Mechanical Engineering of a Synthetic Phenol Plant

BY FREDERICK POPE

The chemistry of synthetic phenol is so generally understood that I will not go into it.

Our general plan is to sulfonate benzol, make the calcium salt, convert that to the sodium salt and fuse with caustic soda, decomposing the sodium phenolate with a mineral acid and refining the phenol by distillation.

STORAGE OF BENZOL AND ACID

The storage tank for benzol must be of ample capacity, closed, of iron and located in a building that can be heated in winter. The building should be well ventilated and electric light bulbs enclosed in airtight or marine fixtures. The benzol should be pumped to the measuring tanks. If the pump is a steam pump, it should be built with a long spacer separating the water end from the steam end. It is a good plan to run this benzol pump with compressed air. It is unwise to handle the benzol with a monteju unless special precautions are taken. This benzol house should be so located as to avoid exposure of this building to fire or sparks caused by passing engines, etc.

Sulphuric acid storage should be of ample capacity. The tanks should be located in a building that can be heated during the winter months. Sulphuric acid can be handled from the storage building to the measuring tanks with a monteju. When convenient, I prefer to force the acid from the storage tanks to the monteju with compressed air, although it is a good practice to draw the acid from the bottom of the tank through an opening in the bottom of the acid tank. This, however, is open to the objection that it is difficult to replace a valve unless the tank is emptied of acid. The building must be well ventilated and the floor provided with drains connected with a sewer so that the floor may be washed off. If possible, both the benzol and sulphuric tanks should be below the track level to allow filling of the tanks by gravity.

MEASURING TANKS

The measuring tanks should be of ample capacity. The sulphuric acid and benzol may be measured by volume, but I very much prefer to mount the measuring tanks on scales, connecting the scales with the pipes to the sulfonating kettle through a spring coil so that the acid or benzol may be weighed. This not only insures accuracy in the process, which may or may not be important, but is economical, which is a consideration with high-priced benzol and sulphuric acid.

There should be a measuring tank for benzol and one for sulphuric acid; these tanks should be vented through the roof. The sulphuric acid tank should be provided with a seal which will dry the air entering the tank.

My general plan is to arrange the tanks so that they shall be filled to an approximate amount; then the scales are adjusted with weights until they balance. One of these weights should represent the exact weight of the charge desired. After the scales have balanced, this weight should be removed and the acid or benzol allowed to run into the sulfonating kettle until the scales balance again and then the supply promptly shut off.

I arrange this by having an indicator from the scale directly in front of the valve controlling the flow from the measuring tank to the sulfonating kettle, having separate inlets for sulphuric acid and benzol, thus enabling the operator to control the supply promptly.

Each sulfonating kettle is equipped with a reflux condenser of the single-pipe type; in form it should be a coil of pipe contained in a tank, which tank is pro-

vided with a water inlet and outlet, the condensing coil is extended at the bottom to connect with the sulfonating kettle and at the top to extend through the roof, the coil so arranged that vapors condensed therein will drain back into the sulfonating kettle.

This coil should be of ample area to give free vent from the sulfonating kettle through the roof out of the building and ample surface to condense the maximum amount of vapor it might receive.

SULFONATING KETTLE

The sulfonating kettle is made of cast iron. Some of the special irons made by various manufacturers have advantages over ordinary cast iron.

The ratio of depth to the diameter must be carefully considered, the depth being somewhat greater than the diameter. The shape of the bottom must also be care-

CROSS-SECTION OF BENZOL BUILDING

fully considered on account of the relation it has to the agitator.

The agitator should be of the propeller type without a bearing at the bottom. I prefer the propeller type of agitator with a single propeller working in a tunnel. The shaft should be of ample size and the propeller shaft and driving pulley carefully balanced.

I prefer to drive the agitator with a belt directly to a pulley on the agitator shaft rather than through bevel gears as is often done. This can be arranged by using quarter turned belt.

The kettle should be provided with a manhole of ample size in the cover and with a thermometer tube extending nearly to the bottom. The thermometer should be a recording thermometer with a flexible connection between the kettle and the instrument. The space between the thermometer bulb and the inside of the thermometer pipe should be filled with precipitated copper or with a mixture of graphite and precipitated copper.

The kettles are steam-jacketed. The steam jacket need not extend more than two-thirds of the height of the kettle. The steam jacket should be provided with a safety valve.

The steam to the jacket of the kettle should enter

through a reducing valve, or a much better arrangement is to use low-pressure exhaust steam.

Cold water should be piped to jacket to cool off accidentally overheated charge.

The steam jacket is connected at the bottom through a pipe to a steam trap. Each sulfonating kettle should have its own steam trap.

The sulfonating kettle may be discharged by using compressed air into the top of the kettle and blowing the charge out through a pipe extending to the bottom, although a much better arrangement, and one that should be used whenever possible, is to have the discharge pipe from the bottom of the kettle, this will pass through a stuffing box in the kettle jacket and is provided with a valve as close as possible to the kettle.

LIME MIXING TANKS

Lime mixing tanks must be of ample capacity. The lime mixers should be iron tanks provided with a powerful stirring device and equipped with an iron basket made in the shape of a segment or a circle, the short dimension of which is $\frac{1}{4}$ the depth of the tank. The depth of the baskets is about $\frac{1}{4}$ the depth of the tank; they may be made of thin plate punched full of small holes or of wire mesh.

The mixer must be piped to receive either hot or cold water and steam. Steam is introduced near the bottom of the tank through a circulating jet.

The tank should be set at such an elevation as to allow the milk of lime to flow to the lime mixing tub by gravity. Pipe connection between the lime mixing tanks and the liming tubs should be as short and as straight as possible and so arranged that the pipes will drain and may be blown out if necessary.

LIMING TUBS

Liming tubs, one for each sulfonating kettle, are made of iron or yellow pine, equipped with a stirring device. The stirring device should be of iron, preferably cast iron.

These tanks are to be located near the sulfonating kettles, piped with cold water and equipped with lead coils on the inside through which cooling water may be circulated.

The liming tubs must be

BENZOL BUILDING—FIRST FLOOR PLAN

LONGITUDINAL SECTION OF BENZOL BUILDING, SHOWING APPARATUS AND MACHINERY

equipped with steam supply to heat the contents of the tub. Steam should be introduced near the bottom, preferably through a circulating heater jet. The outlet should be as close as possible to the bottom and on the side of the tank.

Either a pump or montejus may be used to supply the filter presses. If a montejus is used, it must be below the tanks so that it can be filled by gravity. If a pump is used, it should be supplied with bronze rods. The connection between the pump or montejus and the liming tubs and between the pump or montejus and filter press should be of ample area and as short and straight as possible, provided with means for blowing out. There should be at least one pump or montejus for each two liming tubs.

LIME FILTER PRESSES

The filter press, which should be the wash type, may be either plate and frame or one of the patented type. I prefer the plain plate-and-frame presses, the frames being designed for a 2-inch thick cake.

There should be ample filtering capacity. The filter presses should be located above the soda tubs.

The best type of filter press for this work is the side inlet type, which does not require holes in the plates or cloths but in which the liquid to be filtered enters through holes in the side lugs and the wash water through holes in the side lugs on the other side.

The press is piped so that it may be washed with either hot or cold water and blown with either air or steam. The discharge from the press is arranged so that it may be discharged to the sewer or to the soda tubs.

SODA TUBS

Soda tubs, one for each sulfonating kettle, are made of iron or yellow pine, equipped with a stirring device. The stirring device should be of iron, preferably cast iron.

These tanks are located on the same level with the liming tubs below the filter presses. They should be equipped with indirect heating coils as well as means for heating with live steam similar to the liming tub. The outlet should be as close to the bottom as possible on the side of the tank.

Either a pump or montejus may be used to supply the filter presses. If a montejus is used, it must be below the tanks so that it can be filled by gravity. If a pump is used, it should be supplied with bronze rods.

The connection between the pump or montejus and the liming tubs and between the pump or montejus and the filter press should be of ample area as short and straight as possible, provided with means for blowing out. There should be at least one pump or montejus for each two soda tanks.

SODA FILTER PRESSES

These are arranged the same as the lime filter presses and all remarks about the filter presses apply here, except that the filter presses are arranged to discharge into either sewer or storage tanks.

The cake from both sets of filter presses is caught in a car mounted on wheels, arranged so that it can be dumped through a chute into a car to receive the cake outside.

It is possible, and in some cases desirable, to have a hopper below the filter press extending the length of the plates and frames so that the cake may be discharged through this hopper into a cart or car below to take it away. Either method admits of economic handling of the filter cake.

STORAGE TUBS

Storage tubs to hold the weak sodium benzol sulfonating solution may be of iron or yellow pine; I prefer to use yellow pine. They must be of ample capacity, large enough to hold at least three days' production of weak liquor.

EVAPORATORS

In a large plant, it is advisable to use a multiple-effect evaporator although in a small plant it is better to use a single effect.

There has been considerable mystery made about evaporators for sodium benzol sulfonate. Any standard machine does the work provided the construction of the machine allows a free and easy circulation of the boiling liquor. Obstructed circulation of liquor will cause the evaporator to scale and lose its efficiency.

A vertical tube, vertical-shell basket-type of evaporator with a splash plate over the basket is the best type to use.

It is a good plan to make the bottom head hinged so that it may swing clear, giving easy access to the tubes for cleaning. However, this is really unnecessary, although desirable, if ample manholes are provided, as the evaporator should run four months without being cleaned.

The shell must be provided with peep holes, gage glasses, etc.

Between each effect and between the final effect, and the air pump, catch-alls or separators must be used to catch any entrained liquid going over with the vapor and so piped that this entrained liquid will be led back to the body of the evaporator.

BENZOL BUILDING—SECOND FLOOR PLAN

The vacuum pump is of the ordinary type of wet vacuum pump and condenser.

The condensed water pump is the ordinary stock type.

The heavy liquor pump is of the Magma pump type; the standard stock patterns of the various pump companies are suitable. Steam pumps are preferable as they are less noisy in operation. It is wise to provide a spare Magma pump, and in a large plant a spare vacuum pump.

A very good arrangement, and one which can be easily made in the case of a double-effect evaporator, is to so pipe the apparatus so that it can be run as a double effect or either shell as a single effect.

In case of a triple-effect evaporator, it is easy to arrange the piping so that it may be run as a triple effect or with any two baskets as a double effect. The object of this is to permit cutting out of any shell for cleaning or repairs without affecting the capacity of the plant.

The heating surface should be designed to evaporate the required amount with 15 lb. pressure as the evaporator should be piped to the 15-lb. line, of which I will speak later.

The heavy liquor from the evaporator is discharged by a Magma pump to the heavy liquor storage tank which is a closed iron tank well covered with insulating material, equipped with steam-heating coils in the bottom and of sufficient capacity to hold three days' output.

The pipe from the Magma pump to the storage tank should be as short and as straight as possible without pockets and arranged so that it may be blown out. The heavy liquor storage tank is located over the drier so that it will feed to the drier by gravity.

SALT DRIER

There are a number of methods of drying the heavy liquor. It may be accomplished with a mechanical drier of the drum or disc type or by drying in open pans.

It is possible, of course, to crystallize the benzol sulphate out of the solution, but that method is open to many objections and I will eliminate it from this discussion.

The best means that I know of is to use a rotary drum drier. It is economical of labor, delivers crystals of a suitable size for fusion, and above all, produces a salt containing a uniform amount of moisture. This is important, for, unless the percentage of moisture in the salt going to the fusion kettles is known, the amount of actual salt used cannot be known.

SALT CONVEYING SYSTEM

The salt from the drum drier discharges over an apron into a screw conveyor parallel to the drum. This screw conveyor discharges into a bucket and belt elevator which discharges the salt on to a conveyor of either screw or belt type and carries it into the fusion building where it discharges into a bin of ample capacity. The salt is drawn from the bottom of the bin into galvanized iron cans—ordinary ash cans being used for this purpose, each can holding 100 lb. salt.

All the foregoing apparatus should be in one building in which there is not any fire or flame of any sort, except the salt storage bin, which is in a second building entirely separate from the first and a short distance from it. This second building will contain the apparatus next described.

FUSION KETTLES

Fusion kettles are cast-iron kettles. The special mixtures of various manufacturers have some advantage over the ordinary cast iron. The kettles are of elongated hemispherical shape and set in a steel shell lined with brick with a layer of asbestos between the brick

and the shell. The kettles rest on an iron top which is supported by the shell and to a certain extent by the brick work.

These may be heated by oil, gas or coal. Oil, however, is the most satisfactory.

There should be a combustion fire pot at the bottom of the setting of smaller diameter than the brick lining. The flame should strike this fire pot tangentially so as to give the gases a whirling motion in the furnace.

The kettles are equipped with a powerful stirring device of cast iron of modified horse-shoe type, that is, the blades are bent backwards in opposite direction so that they will throw the molten mass upward as well as around. It is a good plan to equip these kettles with breakers to further agitate the whirling mass.

The kettles are equipped with a thermometer tube, which may be of double extra heavy pipe with end

CROSS-SECTION OF FUSION BUILDING

welded or preferably of a rod of wrought iron bored out with a gun bit. The thermometer should be of the recording type with a flexible connection from the bulb to the recording instrument.

The kettles may be discharged through a bottom opening or by ladling out the fused mass. I have found the latter method to be the more satisfactory. The disadvantages of a bottom discharge more than outweigh its evident advantages.

The best general arrangement of the fusion kettles is to have them level with the floor so that the caustic soda and the salt may be charged into the kettle from the floor level. The kettles should be arranged in two rows with the floor level lower than the main floor level between them.

METHOD OF HANDLING FUSED SODIUM PHENOLATE

In the center of the space between the rows of kettles, a trough extends from one end to a conical-bottom tank at the other. This tank is provided at the bottom with a grid covered with a wire screen and at the bottom of the cone with a centrifugal pump discharging into the other end of the trough. When this tank is nearly filled with water and the centrifugal

pump started, it discharges a stream of water into the far end of the trough running back into the tank.

The hot fused sodium phenolate and excess of caustic, without any previous cooling, can be ladled from the kettle directly into the water in this trough, which readily dissolves the same. When a kettle has been entirely discharged the system is arranged so that the pump will discharge into the decomposing tanks.

WEAK ACID TANKS

These are yellow pine or cypress tanks, lead-lined, located over the decomposing tanks or acidulators. The space over these tanks must be well ventilated.

DECOMPOSING TANKS OR ACIDULATORS

These are of iron. Under some conditions it is necessary that these shall be lead-lined or made of cast iron. They shall have a cone bottom. Weak acid is brought to these tanks from the weak acid tank through a lead pipe which discharges near the bottom. They are arranged so that either compressed air or steam can be admitted near the bottom of the tank.

These tanks discharge through a sight glass arranged with a three-way cock so that the tanks can discharge to the sewer or to the crude phenol tank.

Between the separator and the sewer there should be a small tank arranged in the shape of a decanter so that in case any phenol is carried out with the waste solution it can be recovered from the top of this tank.

CRUDE PHENOL TANKS

These are sheet iron tanks provided with indirect steam-heating coils. These should be of sufficient capacity to hold three days' production of crude phenol. From the fusion kettles to the crude phenol tank, the apparatus is all in one building.

REFINING STILL

The refining still, which is located in the first-mentioned building, should be of column type with dephlegmator. The condenser should contain silver tubes and all portions of the condenser coming in contact with the finished phenol should be silver or silver-lined. The pipes

PLAN SHOWING LOCATION OF APPARATUS IN FUSION BUILDING

from the condenser through the watch glass to the phenol tank should be silver-lined and the valves (flanged gate valves) extra heavily silver-plated. The phenol receiving tank should be enamel-lined and all valves and fittings in connection therewith should be silver or silver-plated.

Cooling water for the condenser, which, of course, is warm water, should circulate from the tank through the condenser, back through a cooler and into a storage tank. The cooler, which is similar to a tubular condenser, is piped with cold water which is so regulated that the temperature of the water in the phenol condenser can be held at a predetermined point. The apparatus in general should be liberally equipped with thermometers.

The phenol still is heated with indirect steam, large coils being used in the bottom of the still, which is a cylindrical tank, laid in a horizontal position. The manhole into this tank should be large enough so that the heating coils may be removed as a whole. This permits of a heating coil without joints. For a still of this type a wet vacuum pump is sufficient. The receiver for water fraction may be an iron tank. Finished phenol is drawn from the phenol receivers into the packages in which it is shipped.

POWER PLANT

Economy of fuel should be carefully considered. The following plan has been found to be very successful.

Engines or turbines exhausting against a back pressure of 15 lb. to the square inch; this 15-lb. exhaust line is carried through the sulfonating building and this steam is used in the evaporator to heat the storage tanks, etc., the condensed water from this system going to a hot-water tank.

The exhaust from all the pumps of every description and all compressors goes into a low-pressure exhaust line which goes to the hot-water heater, the feed-water heater and in winter to heat the building. The condensation from the heating system when in use goes to the hot-water tank.

There is a connection from the high-pressure steam lines through a reducing valve into the 15-lb. steam line in case the supply of steam to the 15-lb. line is insufficient. There is also a connection from the 15-lb. line through a reducing valve into the low-pressure line, in case there is an excess of steam in the 15-lb. line. There is a connection from the 15-lb. line to the low-pressure line through a reducing valve, in case the

supply of steam in the low-pressure line is insufficient and a connection from the low-pressure line to the boiler-feed water heater and to the atmosphere in case there is an excess of steam in the low-pressure line.

The boiler plant and the engine room, aside from the points mentioned, are of ordinary construction.

All machinery of the plant must be driven preferably by motors supplied with current from the generators which are driven by the turbines. Alternating current should be used to avoid any possibility of sparks which are common in direct-current motors.

In such a plant as this, the labor cost and fuel cost per pound of phenol is very low.

The best type of building construction is steel frame, brick walls, with a roof made of gypsum blocks.

The cost of a well-designed phenol plant to produce 10,000 lb. of phenol per day, brick and steel buildings, power plant, complete, is about \$200,000. A plant for making 20,000 lb. a day costs about \$250,000.

The Viscosity of a Thermolized Paraffin Base Oil

BY GUSTAV EGLOFF AND ROBERT J. MOORE

In the study of the thermal decomposition of hydrocarbon oils the physical constant of viscosity is of some significance. In this note the effect of temperature and rate of oil flow upon the viscosity of the thermolized oil has been studied.

The paraffine base oil used was subjected to temperatures ranging from 500 deg to 700 deg C. and rates of oil flow from 12 to 36 gal. per hour. The viscosity of the oils was determined by means of the usual method in oil technology the Standard Engler¹ Viscometer.

Experimental Data

Table 1 and Fig. 1 give the experimental data on the viscosities of a paraffin base oil thermolized at varying temperatures and constant rate of oil flow of 16 gal. per hour.

Table 2 and Fig. 2 give the experimental data on the effect of rate of oil flow on the viscosity of a thermolized paraffin base oil at constant temperature of 600 deg. C.

TABLE 1.

THE VISCOSITIES OF A PARAFFIN BASE OIL THERMOLIZED AT VARYING TEMPERATURES AND CONSTANT RATE OF OIL FLOW OF SIXTEEN GALS. PER HOUR

Temperature, deg. C.	500	550	600	650	700
Viscosity Engler Deg.	1.104	1.151	1.245	1.094	1.055

TABLE 2.

THE EFFECT OF RATE ON THE VISCOSITY OF A THERMOLIZED PARAFFIN BASE OIL AT CONSTANT TEMPERATURE

Rate, gallons per hour	12	16	22	30	36
Viscosity Engler Deg.	1.330	1.245	0.906	1.151	1.161

Discussion of Data

In the thermal decomposition of a paraffin-base oil the viscosity of the oil increased with increase of temperature to a maximum and then decreased as the temperature increased within the limits of the experiments. In Table 1 the maximum viscosity is noted at 600 deg. C. of 1.245 and the minima of 1.104 at 500 deg. C. and 1.055 at 700 deg. C. The effect of rate upon the viscosity at constant temperature of 600 deg. C. gave a minimum of viscosity 0.906 at 22 gal. per hour, and maxima of 1.330 at 12 gal. per hour and 1.161 at 36 gal. per hour.

Fig. 1 gives a maximum point and two minima in the viscosity with change of temperature; while a change

in rate gives a minimum and two maxima in Fig. 2. Greater decomposition of the starting oil takes place as the temperature is increased. This is a common phenomenon of the cracking of oils.² The opposite is the case when the rate of oil flow is increased, which is equivalent to the time factor³ in chemical reactions. As the oil is passed through a heated tube with increased rapidity as exemplified by changing the rate of oil flow from 12 to 36 gal. per hour, the changes taking place in the oil grow less and less until a rate is reached where no decomposition at all takes place. At

FIG. 1—VISCOSITY OF A PARAFFIN BASE OIL THERMOLIZED AT VARYING TEMPERATURES AND CONSTANT RATE OF FLOW OF 16 GAL. PER HOUR

12 gal. per hour and 600 deg. C. maximum decomposition of the starting oil took place with a resulting greater viscosity of the oil than the maximum temperature of 700 deg. C. and 16 gal. per hour gave. In short, the time factor in this series of experiments had a greater effect upon the viscosity than the temperature factor.

Theory

For mixtures of pure liquids the physical constant of viscosity is rarely a strictly additive property. The viscosity deviates from the additive law due to volumetric, thermal or molecular action between the constituents of the mixture. Perhaps this is due to the breaking down or building up of complexes in certain liquids due to surface tension⁴ and viscosity relationships which would indicate that solution of one liquid in another is quite similar in character to thermal effects upon the solution. Wijkinder,⁵ Lineberger,⁶ Thorpe and Rodgers⁷ have found experimentally that the viscosity of a mixture of miscible and chemically indifferent liquids is rarely if ever, under all condi-

tions a linear function of the composition of the mixture.

After thermal treatment the paraffin-base oil at 500 deg. C. was mainly composed of the paraffin and ethylene series of hydrocarbons with small amounts of aromatic compounds present. At 600 deg. C. the proportion of the aromatic series increased at the expense of the aliphatic hydrocarbons, while at the temperature of 700 deg. C. the thermolized oil contained mainly aromatic compounds of the benzene series. A satisfactory explanation of an increase of viscosity with increase of temperature and then a decrease as the temperature reached 700 deg. C. cannot be given as the complexity of the mixture of hydrocarbons is too great.

FIG. 2—EFFECT OF RATE OF FLOW ON THE VISCOSITY OF A THERMOLIZED PARAFFIN BASE OIL AT CONSTANT TEMPERATURE

From the data⁷ of the viscosity of individual hydrocarbons of the paraffin, ethylene and benzene series some approximations may possibly be made as to the maxima and minima of the viscosities of the oils reported in this investigation. Dunsten and Thole in their book, "The Viscosity of Liquids," have shown that in homologous series there is an increase in viscosity corresponding to an increment of CH_2 , but the increase tends to diminish as the molecular weight increases. Increase of carbon atoms in the molecule decreases the viscosity. Unsaturation increases the viscosity of the liquid. The viscosity of the benzene series is greater than the paraffin series.

As the temperature increases the viscosity of the treated oil increases which may in part be explained upon the basis of increased formation of the aromatic compounds of the benzene series and unsaturated hydrocarbons up to a definite temperature.⁸ As the decomposition reaction continues heterocyclic compounds are formed of naphthalene, anthracene and their methyl derivatives¹⁰ and higher polycyclic hydrocarbons of which little is known. The greatly increased carbon content in the hydrocarbons of the latter type, one may infer from the work of Rellstab¹¹ indicated that

the viscosity decreases with increase of carbon content. The physical constant viscosity is an exceedingly complex phenomenon, however, and in view of the immense amount of work yet to be done upon the polycyclic hydrocarbons, the above theoretical considerations as applied to thermolized oils, are not inclusive.

Summary

1. A theoretical explanation has been given as to the phenomena of viscosity as applied to complex mixtures of aliphatic and aromatic hydrocarbons resulting from the thermal decomposition of a paraffin base oil.

2. The viscosities have been determined of a paraffin base oil thermolized at varying temperatures. The maximum in viscosity 1.245 was found to be at 600 deg. C. and constant rate of flow of 12 gals. per hour. The minimas of 1.104 at 500 deg. C. and 1.055 at 700 deg. C. at the same rate are recorded.

3. The effect of the rate of oil flow upon the viscosity of a thermolized paraffin base oil has been determined. The minima in the viscosity was found to be 0.906 at 22 gal. per hour and maximas of 1.330 at 12 gal. per hour and 1.161 at 36 gal. per hour.

Measurements of Resistivity and Thermal Electromotive Force of Samples of Calcium, Aluminium, Magnesium, Alloys of Aluminium and Magnesium and the Thermal E. M. F. Curve of Nickel vs. Nichrome

The writer is greatly indebted for the samples herein after known as Nos. 1 to 6 inclusive, to Dr. W. R. Whitney who presented them to him to be used for experimental purposes. He is also indebted to the Aluminum Company of America for the very pure sample of aluminium and its chemical analysis. The measurements of resistivity and a report on the results obtained were made by the writer's students, Mr. L. D. Howell and W. van B. Roberts. The data on the thermal e.m.f.'s were obtained and reported on by the writer's students, Mr. A. J. Mundt and Mr. B. S. McCutchen. The curve of the thermal e.m.f. of nickel vs. nichrome was obtained for the writer by Mr. L. A. Cavalcanti.

Resistivity Measurements

The measurements made were confined to the temperature range 20° to 150°C. Resistivity measurements were made on the following samples, all in the form of wires under 0.23 cm. in diameter:

- (1) was pure magnesium.
- (2) was 87.5% aluminium + 12.5% magnesium. Cold drawn.
- (3) was 10% aluminium + 90% magnesium.
- (4) was 90% aluminium + 10% magnesium. Cold drawn.
- (5) was 90% aluminium + 8% magnesium + 2% nickel. Cold drawn.
- (6) was pure calcium.
- (7) was 99.67% Al., 0.16% Si., 0.15% Fe., 0.02% Cu. and was annealed by heating red hot and cooling in air.

*FOREWORD.—This is the first of a series of reports which the writer plans to give in the columns of METALLURGICAL AND CHEMICAL ENGINEERING of work done by the writer and students and assistants working under his direction, at and with the facilities of the Palmer Physical Laboratory, Princeton, N. J.

(8) was the same wire as (7) but not annealed by us.

APPARATUS USED

Kelvin double-bridge (Leeds and Northrup, catalogue number 4307).

Sensitive galvanometer (Leeds and Northrup, catalogue number 2280).

Wheatstone bridge.

Galvanometer (Leeds and Northrup portable type).

A German silver coil of about twenty ohms for heating.

A well aged copper coil used as a resistance thermometer of about 6.5 ohms and of about the same length as the samples.

Adjustable resistances, pan of oil, mercury thermometers, storage cells.

PROCEDURE

The resistance of the specimens was measured with a Kelvin double-bridge used with a Leeds and Northrup sensitive galvanometer. (Consult, *Methods of Measuring Electrical Resistance*, by E. F. Northrup. See, for general treatment of the Kelvin double-bridge, *arts.* 609-614, and for description of particular apparatus used, *arts.* 706, 1505.)

The specimens were held in a frame under suitable clamps. The potential point contacts were obtained with knife-edges held down with spring-pressure. The frame and sample were placed in a long narrow tank under kerosene oil. A thoroughly aged copper coil about 0.4 cm. in diameter and of about the same length as the distance between potential points, approximately 38 cms., was located close alongside the specimen. This coil, used as a resistance thermometer, served as the standard of temperature. The relation between its resistance and temperature was previously very accurately determined at the ice-point and the boiling-point of water. As the resistance-increase of copper with temperature in the temperature range 0° to 100°C. is strictly linear, the temperature of the coil, and hence the average temperature of the sample in close association with the coil, was very accurately determined from a resistance measurement of the coil. As an additional precaution against error in determining the temperature of the sample, the oil was stirred at the time a measurement was being made and all readings were taken when the temperature of the oil was nearly stationary.

The heating of the oil was effected by means of a heating coil of resistance wire immersed in it. As the oil cools slowly, when the heating current is turned off, a more rapid lowering of the temperature was occasionally obtained by adding cold oil to the tank. By stirring and adjusting the current through the heating coil it was not difficult to maintain the oil at nearly equilibrium temperature at the intervals at which measurements were made. A resistance coil, like the one described above, is very superior to a thermocouple, resistance-thermometer or other device which gives the temperature at a point. The reason is that the resistance-thermometer coil being of the same length as the distance between the potential points of the sample being measured gives the mean temperature of the sample between potential points, and, if the sample has a nearly constant temperature coefficient, inequalities in the temperature of the oil or the sample between the potential points introduce no error; for it can be considered that the resistance of the coil gives a mean temperature and since the variation of temperature along the length of the coil and sample is the same, the resistance of the sample is its resistance at the temperature deduced from the coil. This is strictly true when the resistance of both the copper coil and the

sample are linear functions of the temperature or if they are similar curves.

To obtain the temperature from the resistance of the coil we referred to a large chart on which the resistance of the coil had been plotted against temperature. The temperature readings were also occasionally verified by using a mercury thermometer carefully corrected and reading to tenths of a degree and hundredths by estimation.

The resistivity of a sample was calculated from the measured resistance. For this calculation it was necessary to measure the length between the potential points and the diameter of the sample. Diameters were obtained by taking the mean of numerous readings of diameter made with a Brown & Sharpe micrometer calipers at various points along the wire and various points around it.

The sensitivity of the measuring outfit was such that a relative error of more than one unit in the last place of decimals would become quite evident. Following a common practise of the writer the Kelvin double-bridge measurements were several times checked during the investigation by transferring without other change in the set up, the current and potential leads to a low-resistance standard known to be correct. When the outfit measured this standard correctly assurance was given that the measurements of resistance were being correctly made.

It seems certain, therefore, that, when measurements on a sample were several times repeated, the sample in the meantime having been heated or cooled between the different measurements, and the resistivity at a given temperature was found to vary (in some cases as much as 2 per cent) this variation cannot be due to errors of measurement. Rather it is shown by the measurements that within rather narrow limits the resistivity of several of the samples depends not only upon the temperature but also upon the previous thermal history of the sample; that is, whether before the measurement it has been heated or cooled and how fast. Slow cooling seems to leave the resistivity slightly diminished.

The absolute values of the resistivities are not only dependent upon the heat treatment of the sample, but are subject to an error in determination which may amount to as much as one-half to two per cent resulting from the difficulty of accurately estimating the cross-section of the samples from micrometer readings of the diameters of the wire. All relative values are certainly correct to within 0.2 per cent.

DATA AND RESULTS

The data used for deducing resistivity from resistance is given in the table below:

DATA FOR DEDUCING RESISTIVITY FROM RESISTANCE

Sample	Length Between Pot. Pts. in Cms.	Mean Diameter in Cms.	Mean Section in Sq. Cms.	k Section Length Resistance Divided by Resistance R	Probable per Cent Error in k and Hence in ρ Estimated
1	42.9	102	00817	0002482	2
2	38.2	1064	00880	0002327	2
3	38.32	1009	00800	0002006	1
4	48.34	10503	00806	000223	0.4
5	38.2	08138	0052	0001362	0.4
6	22.4	12165	01192	00521	0.4
7	38.9	2254	0399	001025	1.0
8	43.1	2254	0399	00111	

The sample of calcium wire (sample No. 6) is (according to a statement made to the writer by Dr. Whitney) taken from a lot made by the Research Laboratory of the General Electric Co. which is probably the first wire ever drawn of pure calcium. No analysis was supplied to the writer but the wire was stated to be of pure calcium. If exposed to damp air it oxidizes slowly

superficially and the sample was preserved under paraffin. The oxidization is not, however, too rapid to prevent the wire from being handled for purposes of micrometering it. It was, of course, under oil while the measurement was being made. The resistivity of this sample was 5.32 microhms at 20°C. and 6.64 microhms at 100°C. per cm². This resistivity of calcium is therefore but slightly greater than pure magnesium which for the sample tested was 4.75 microhms per cm² at 20°.

It was found that although aluminium and magnesium both have low resistivity their alloys have a considerably higher resistivity than either of the constituents and that increasing the proportion of magnesium greatly increases the resulting resistivity. Thus, at 20°C. sample No. 4 consisting of 90 Al. + 10 Mg. has a resistivity of 8.28 microhms, while sample No. 3, consisting of 10 Al. + 90 Mg. at the same temperature has more than twice the resistivity, 19.18 microhms per cm².

The curve sheet, Fig. 1, embodies the results obtained in the measurements and will be understood without further comment. However, as the resistivity varied with repeated heatings and coolings, another curve, No. 2, is given which shows the striking manner in which this change in resistivity occurs in the case of the alloy 90 Mg. + 10 Al., namely, sample No. 3. The occurrence of this phenomenon happened to some extent with all the samples and it took a very long time to conduct the many series of measurements required to satisfy ourselves that the resistivity of the samples was really changing and that the measurements were in no wise in error.

As the writer has stated in previous communications many metals and most alloys when in the solid state

FIG. 2—RESISTIVITY OF ALLOY 90 PER CENT Mg. AND 10 PER CENT AL.

Points 1 to 2, slow heating; 2 to 1, slow cooling; 1 to 6, slow heating; 6 to 7, slow cooling; 6 to 8, heated by removing metal and pouring in hot oil. It will be noted that the last curve up is identical with the previous one down.

will have a resistivity which is more or less dependent upon past physical history, and if, therefore, we wish to obtain resistivity measurements for samples which have a resistivity dependent only upon temperature and chemical composition, we must bring the samples into the molten state. (See numerous articles by the writer in the *Journal of the Franklin Institute*, beginning in February, 1913.) In the case, however, of a very pure metal as copper, platinum or nickel which has been drawn into wire and then thoroughly "aged" by prolonged heating, the resistivity will become a function of the temperature only, if the temperature is maintained below that at which the sample was aged. If this were not so pure metals could not be relied upon as satisfactory pyrometric substances for use in resistance thermometry.

Determinations of Thermal Electromotive Force

The object sought in the series of measurements described below was to determine the thermal e.m.f. at various temperatures developed in a thermocouple made from the General Electric Company's samples Nos. 1 to 6 as described above, also the sample of aluminium, No. 7, all against pure copper; and an additional series of measurements were thought to be desirable on the combination pure nickel vs nichrome, for reasons which will appear later.

Arrangements were made so that all readings of e.m.f. would be given to the units place in microvolts. With the exception of the nickel vs. nichrome combination, which was studied in a slightly different manner, the following procedure was adopted:

The method of measurement.—Accurate temperature points were obtained by making use of the following fixed points: The boiling-point of water, the freezing-point of tin, and the freezing point of zinc. The e.m.f.'s of the various samples developed at these points when the cold junctions of the couples were in an ice-bath were read with a potentiometer. The apparatus employed consisted of a Leeds and Northrup potentiometer and galvanometers, a Weston standard cadmium cell, a small electric furnace wound with nichrome ribbon, a small Dewar flask filled with cracked ice, a hypsometer and some small accessories. The electrical connections employed are shown in the diagram Fig. 3.

The first step was to construct thermocouples using the various samples against Cu. The details of construction are sufficiently shown in Fig. 3. A is a small

FIG. 1—CURVES OF RESISTIVITY AS FUNCTION OF TEMPERATURE

quartz tube, and B is a protecting tube of Marquardt ware. It was found impossible to weld the junctions and hence a mechanical connection was resorted to. This was made by flattening the ends of the wires and wrapping them with fine Cu. wire. The apparatus was set up as shown in Fig. 3 for obtaining the melting points of metals and the hot junction was placed in the hypsometer for the 100° point.

The e.m.f.'s generated were read, while steam was

FIG. 3—EXPERIMENTAL ARRANGEMENT

pouring out freely. The barometer was read and the correction for boiling-point found. Six readings were taken and the average value used. The other junction during these experiments was kept at zero degrees Centigrade by being placed in the Dewar flask filled with cracked ice.

The tin-point and zinc-point were obtained as follows: The metal was placed in an aluminum thimble which was located in a small, vertical, nichrome-wound tubular furnace. The inner wall of the heating tube was lined with a graphite tube so that when the furnace was heated above a red heat a reducing atmosphere would be developed. This is desirable and, in fact, necessary, when one is obtaining the copper-point, to preserve the metal free from oxidation on its surface.

The hot junction of the couple was slipped into a small tube of Marquardt and this in turn was slipped into a very thin-walled graphite tube closed at the bottom end. The hot junction thus protected was immersed in the molten metal.

The heating current of the furnace was either shut off or reduced and readings of e.m.f. were made on the potentiometer at frequent intervals as the metal cooled. As is well known the temperature of the metal holds stationary while solidification is occurring and the e.m.f. of the couple read at this time is the e.m.f. which it develops at the temperature at which the metal freezes. Both in the case when obtaining the tin-point and the zinc-point the metal was heated and allowed to cool until quite solid and then again heated and again allowed to cool, this being repeated at least four or five times. The successive readings of the e.m.f. taken at the freezing-point of the metal were found to agree almost exactly.

The method described above was followed for all samples except No. 6 (pure calcium) for which the following procedure was adopted. The hot junction was placed in a kerosene bath which was heated electrically, the cold junction being maintained at zero degrees Cen-

tigrade in the Dewar flask. The temperature was read by means of a resistance thermometer, all points being determined while the oil-bath was cooling and after it had been well stirred. For points above 100°C. the hot junction was placed in a protecting tube filled with Crisco, which stands a much higher temperature than oil. A mercury thermometer was bound to this tube and the unit so made was placed in the furnace.

Tables I and II of data obtained on sample No. 4 (90 Al + 10 Mg vs Cu) and sample No. 6 (Ca vs Cu) will explain the manner of taking the readings and the general character of the results obtained:

89	840
90.4	968
92	1000
96	1027

The curve for calcium (Fig. 4) was plotted from the above results. An attempt was made to observe the e.m.f.'s developed up to 335 degrees, using Crisco to protect the wire from oxidation. No consistent results, however, were obtained due to the occurrence of frequent open circuits at the hot junction caused by oxidation of the calcium wire at the joint. The point indicated as the freezing point of tin on the Summary Data Sheet (Table II) was found by extrapolation.

The direction of the e.m.f.'s generated was found to be through the hot-junction from the sample to the Cu. in every case.

The results contained in the following table are all plotted in curves Fig. 4.

The curve, Fig. 5, for the thermal e.m.f. of very pure nickel vs nichrome (made by Driver-Harris Co.) was obtained for the writer by Mr. L. A. Cavalcanti and is interesting from two standpoints. First it gives results obtained by a well-known method which may be used with great ease by any one for very accurately calibrating a thermocouple up to the temperature of freezing copper (1082° C.), no use being made of any instrument, thermocouple or resistance thermometer to serve as a standard of temperature.

The method gives with great simplicity five accurate points for tracing a curve, which number is quite sufficient for ordinary purposes. The method is quite similar to the one, just described, which was used in determining the thermal e.m.f.s. of the different General Electric Co.'s samples.

A small nichrome-wound furnace arranged to stand vertical, with a chamber large enough to hold a crucible of graphite one inch in diameter and about three inches high, serves admirably the purpose of a heat-producing apparatus. The bottom of the furnace-heating tube should be tightly closed and the thermocouple tube should be passed through a small hole in the cover of the furnace, which should fit tightly (see Fig. 3). The graphite of the crucible, immediately a red heat is obtained, converts the atmosphere in the furnace chamber into a reducing atmosphere which preserves the surface of the metals (Sn, Zn, Sb and Cu used for giving fixed points of temperature), free from oxidation.

A crucible should be provided for each metal employed and each crucible about two-thirds filled with a partic-

ular metal, may be used over and over again, and so serve the purpose of giving a fixed-point of temperature for many thermocouple-calibrations.

There should also be provided as many graphite tubes (closed at the bottom and with a wall less than a mm. thick), as there are metals used. These graphite tubes serve as a cap (see Fig. 3) which fits over the end of a

FIG. 5—THERMAL E.M.F. CURVE FOR NICHROME VERSUS NICKEL THERMOCOUPLE

thermocouple, loosely. This cap will prevent any undue strain being exerted on the casing of the thermocouple when the metal, in which the thermocouple is immersed, freezes and contracts and the thermocouple may be removed from the crucible containing the solidified metal without reheating.

It was with this method, as just described, that each of the points, except the boiling point of water, was obtained for plotting the curve shown in Fig. 5. The e.m.f. was, of course, read with a potentiometer at the time a metal was in the process of freezing, and the temperature and e.m.f., consequently, remained for a certain interval constant.

The curve, Fig. 5 is, secondly, very interesting because it shows that there is an interval of temperature (between 350° and 500° C.) in which the curve makes a slight inflection, the e.m.f. not increasing in the regular way with increase in temperature that it does outside this interval. This is probably due to the fact that nickel has a recalcence point in the neighborhood of 360° C. As a combination of any of the metals of the iron group with nichrome give a high thermal e.m.f., and as all these metals have high melting-points they would naturally be considered very useful as one metal in a combination for a base-metal thermocouple. The fact, however, that the curve shows a change in its regular course near a recalcence point of a metal belonging to the iron group, should at least put one on his guard against too implicit reliance on the accuracy of the temperature indications of a thermocouple in which nickel or nichrome forms one element, in the neighborhood of the temperature of recalcence. This change in the course of the curve may not exist in the combination cobalt vs. nichrome; but should be looked for very carefully.

In the combination nickel vs. nichrome the e.m.f. acts to send current from nickel to nichrome through the hot junction.

The experimental work described above was done between January and March, 1916.

FIG. 4—CURVES OF THERMAL E.M.F.S.

The Principles of Filtration

BY D. R. SPERRY

Filtration consists of the process of separating the solids from a mixture of solids and liquid by causing the liquid to flow away from the solids through a porous mass the openings of which are too small to allow passage of the solids.

The porous mass is called the filtering medium and is composed of two parts: that which was provided in order that filtration might begin, called the filter base, and that which was formed during filtration, called cake, consisting of the solids which were too large to pass through the openings of the porous mass.

The mixture of solids and liquid is called the mixture, while the liquid which was separated from the mixture is called the filtrate.

THREE INDISPENSABLE CONDITIONS OF FILTRATION

There are three indispensable conditions of filtration:

1. There must be a difference of pressure between the two faces of the porous mass, the higher pressure being on the side in contact with the mixture. The intensity of this pressure difference must be great enough to cause the liquid to flow through the porous mass. Without this pressure there would be no flow through the filtering medium, and hence no filtration.

2. There must be a filter base. If there is no filter base, there is no porous mass with which to start filtration, and therefore no filtration at all. In practice the filter base often consists of cloth or paper.

3. There must be a filter. A filter consists of a device employed to support the filter base and to confine the mixture so that the same may be placed under pressure and in contact with the filter base.

Inasmuch as there is a difference in pressure between the two sides of the filtering medium it follows that the low-pressure side must be supported. If this is not done the filter base will not remain in place and filtration will not result. Also, if the mixture is not held in place on the filter base it will flow away and filtration will not take place. A filter is therefore indispensable.

FILTRATION IN DETAIL

In order more clearly to comprehend the process of filtration, Fig. 1 is presented.

At *A* a mixture is shown in a confined space and in contact with a filter base *X*. Directly below is shown a receptacle to catch the filtrate. At the instant shown, filtration is at the very point of starting. Here can be observed the importance of the filter base, for at this step it comprises the entire filtering medium. At no other point in the process of filtration is this true. It initiates filtration, supplying for the time being the porous mass which later will be composed mostly of solids from the mixture.

At *B* flow of the liquid through the porous mass has proceeded for a certain length of time. The liquid or filtrate has collected in the receptacle below, while the

solids, unable to pass through the porous mass with the liquid, are necessarily left as a deposit *Y* upon the filter base. The filtering medium now no longer consists of the filter base only, but of two parts, the filter base plus the deposited solids or cake. It should be observed that the liquid now has to pass through a porous mass of greater thickness than in the case at *A*; consequently, assuming the pressure of the mixture to be constant, its rate of flow will be decreased.

At *C* an interval of time has elapsed from the state at *B* sufficient to double the amount of filtrate caught in the receptacle. As a result, assuming that equal quantities of liquid carry equal amounts of solids, the thickness of cake is twice that found at *B*. Since the liquid must flow through this greater depth of porous mass, its rate of flow is necessarily much less at *C* than it was at *B*.

At *D* still another interval of time has passed—enough so that the filtrate in the receptacle is twice that found at *C*. This doubles the thickness of cake over that found at *C*, resulting in a further decrease in the rate of flow of the liquid.

TWO PROCESSES AT WORK

A careful study of Fig. 2, in the light of the details

FIG. 2—CONDITIONS DURING ONE INSTANT OF FILTRATION

just given, will disclose the fact that there are two distinct and constantly changing processes going on, as follows: (1) Flow of liquid through porous mass; (2) building up of the porous mass or cake. These two processes are constantly changing because the liquid as it flows into the cake is continually leaving its solids behind, thus constantly increasing the thickness of the

porous mass, while simultaneously with this action the liquid is continually decreasing its own rate of flow, due to the increasing thickness of solids through which it has to pass.

It is now evident that if an expression showing the relation between these two processes can be devised and the laws of each are determined, the two can be combined in a known relation, thus deriving the fundamental laws of filtration.

RELATION BETWEEN THE TWO PROCESSES

In Fig. 2 is illustrated a cross-section of a filter in which the process of filtration is proceeding. A study of the instantaneous conditions there depicted reveals the fact that the rate of flow of the liquid through the porous mass is, at that moment, equal to the rate of flow which would obtain were there liquid only above the same. This can be best comprehended by considering the layer of liquid *A*, for it can readily be seen that during the instant this layer is entering the cake the conditions are the same as though liquid only were above. In actual conditions, of course, the particles of solids are not liable to be equally spaced in the liquid, but the effect in principle is the same.

The relation between the two processes—flow through cake and thickness of porous mass—can now be set down as follows: Rate of flow at any instant = rate of flow for liquid only through the thickness of porous mass at that instant.

The relation between the two processes being now

FIG. 1—FOUR STAGES OF FILTRATION

established, the next step is to investigate separately the laws governing each, and then by means of the common relation combine the two sets of laws to form the fundamental laws of filtration.

The First Process—Rate of Flow Through the Porous Mass

To investigate the laws governing the flow of liquids through a porous mass, the apparatus shown in Figs. 3 and 4 was employed. The method consisted in actually depositing a cake by the process of filtration upon a suitable filter base, and then measuring the rate of flow through the cake under various pressures with clear liquid only.

The apparatus consists of a small filter press having one plate and frame, the filter base being in a horizontal plane. This latter was done in order to minimize the effects of sedimentation as much as possible in order to secure a cake of uniform thickness. At the beginning of the test a piece of No. 10 duck *E* was laid upon the filter plate *F*. Upon the duck was placed frame *D*, while upon *D* was placed the head *C*, with a thin packing between them. Pressure was then applied mechanically so as to squeeze the pieces together. The pipe connection on the head was piped to a hand pump *A* on one side, and to a general water system *B* on the other. Valves were placed so that feed could be obtained from either source.

In the mixture tank were placed 3 quarts of water and $1\frac{1}{2}$ ounces of kieselguhr.* This material was selected because the particles of which it is composed are insoluble in water and quite rigid, thus avoiding errors due to leaching effects or change in shape of the solids.

After thoroughly agitating the mixture it was pumped into the filter chamber at 60 lb. per square inch pressure. This pressure was continued until about 1 quart of filtrate was obtained. At this point pumping was discontinued and the valve leading to the general water system was cracked just enough to keep the pressure constant at 60 lb. per square inch. The valve leading to the pump was then closed, and in order to assure complete deposition of the solids which were still in suspension within the frame, water was allowed to run from the filter until about three-fourths of a quart had escaped. The rate of flow was then measured, the gage showing 60 lb. per square inch.

Next the valve to the general system was closed just enough to show 50 lb. per square inch on the gage. The rate of flow was then measured. This process was kept on in decrements of 10 lb. per square inch until 10 lb. per square inch was reached, at which point the valve was closed entirely, the head removed and the approximate thickness of cake measured. Temperature was maintained at constant value throughout the test. The data obtained are given in Table I.

*A typical analysis of the Kieselguhr as used is given by the producers thereof as silica, SiO_2 , 89.17 per cent; alumina, Al_2O_3 , 1.65; iron oxide, Fe_2O_3 , 0.54; titanium oxide, TiO_2 , 0.03; lime, CaO , 0.54; magnesia, MgO , 0.52; loss on ignition, 6.64.

FIG. 3—EXPERIMENTAL FILTER PRESS

TABLE I

Date of test, March 29, 1915.
Place of test, Basement Laboratory, 178 Union Avenue, Batavia, Ill.
Temperature, about 65 deg. Fahr.
Filter base, No. 10 duck.
Mixture, $1\frac{1}{2}$ ounces of kieselguhr in 3 quarts of water.
Filtering area, $1/20$ sq. ft.
Apparatus, as shown in Figs. 3 and 4.
Pump, $1\frac{1}{2}$ -in. x 3-in. stroke, single-acting, hand-operated.

Method of Procedure:

- (1) From 5:16 p. m. to 5:18 p. m. pumped mixture in filter at 60 lb. per square inch until 1 quart of filtrate was obtained.
- (2) Opened valve to water system at 60 lb. per square inch and closed valve on pump line.
- (3) Allowed water to flow from filter until about 12 ounces was collected.
- (4) Regulated pressure by cracking water valve and made reading as follows:

Water Pressure	Time of Reading, P. M.	Flow of Water, Fluid Ounces	Rate of Flow in Cu. Ft. Per Hr.
60	5.22 to 5.25	26	4.06
50	5.26 to 5.29	21	3.28
40	5.30 to 5.33	17	2.66
30	5.34 to 5.37	12.5	1.95
20	5.38 to 5.41	8.5	1.33
10	5.43 to 5.46	4.2	.656

Remarks

Cake found to be about $\frac{1}{2}$ in. thick.

Cloth showed grooving or deformation apparently the same as observed at conclusion of tests made with ascending pressure increments.

Cake showed very faint coloration on surface in contact with water only.

The plotted results from the test are shown in Fig. 5.

Perhaps the most interesting result of this test is the fact that it shows that the rate of flow of the liquid through the cake varies as the first power of the pressure.

So straight a curve was not obtained, however, at the

FIG. 4—VIEW OF FILTER, OPEN ON LEFT, CLOSED ON RIGHT

FIG. 5—EFFECT OF PRESSURE ON RATE OF FLOW OF WATER THROUGH FILTER CAKE OF KIESELGUHR

first trial. In previous tests the rates of flow were measured in ascending instead of descending increments. Under these conditions it was quite impossible to secure a straight-line curve. Careful examination of the cakes disclosed the fact that this was due to the drawing away of the edges of the cake from the sides of the frame due to the deformation of the filter cloth with the increasing pressure. This condition resulted in the exposure of an abnormal surface and the development of shorter porous paths to carry away the liquid. This caused the curve to bend upwards with increasing pressure.

A slight brownish coloring left by the liquid as it entered the cake showed conclusively that it gained entrance on the sides as well as top. A study of the cloths at the finish of ascending and descending tests, the maximum pressure being the same in both cases, showed a deformation or ridging the same in each instance. This would indicate that once a filter cloth is deformed by pressure the deformation becomes permanent. Examination of descending test cakes showed a brownish coloring on the top only, indicating that the liquid did not enter the cake at the sides.

FLOW THROUGH FILTER CAKE A CAPILLARY PHENOMENON

To many the fact that the rate of flow through a filter cake varies as the first power of the pressure will be looked upon as rather singular. Most would expect the rate of flow to vary as the square root of the pressure according to the law of falling bodies and the various flow-through-pipes formulas found in works of hydraulics and in handbooks.

It has long been known, however, that there are two distinct kinds of flows of liquids through tubes, namely, sinuous and non-sinuous. The first has been also called eddying, while the second has been called eddyless, parallel, direct or capillary flow.

If water under very calm conditions is caused to flow through a smooth tube with flared inlet at very low pressure, and then the pressure is very gradually increased, the flow for a time through the tube is very smooth and even, the rate of flow varying as the first power of the pressure. It has been shown that during this period the liquid flows in parallel lines without eddies or sinuosities. This has been shown by the injection of coloring matter in the liquid while flowing through a transparent tube.

As the pressure increases a point is finally reached at which quite suddenly the rate of flow commences to vary as the square root of the pressure, and simultaneously with this event the flow of the liquid is shown to break up into smoky convolutions caused by eddies and

sinuosities. This point is called the critical point, and marks the moment of change from one type of flow to the other.

The cause of the difference in behavior of the flow in respect to pressure is said to be due to the fact that in the non-sinuous flow the chief resistance to flow is caused by the viscosity of the liquid, while in the sinuous flow the chief resistance is that due to friction between the liquid and the walls of the tube. These two types of liquid flow were very beautifully pointed out and explained in 1883 by Prof. Osborne Reynolds, F.R.S., in a paper¹ entitled "An Investigation of the Circumstances Which Determine Whether Motion of Water Shall Be Direct or Sinuous, and of the Law of Resistance in Parallel Channels." This paper is well worth reading, and there will be found therein a logarithmic homologue of the "pressure-rate of flow" curve through a tube. The critical point is very interestingly indicated by the point at which the slope changes from 1 to 0.5.

A later paper on this same subject² by Professor Coker and Mr. Clement, 1903, communicated by Prof. Osborne Reynolds, F.R.S., entitled "An Experimental Determination of the Variation with Temperature of the Critical Velocity of Flow of Water in Pipes," is also of much interest.

Poiseuille,³ in 1842, developed from experimental data an empirical formula for sinuous or eddyless flow as follows:

$$v = \frac{\pi p r^4}{8lu}$$

Where p = pressure, r = inside radius of tube, l = length of tube, v = vel. of flow, u = coefficient of viscosity.

Later this empirical formula was derived by purely theoretical considerations.⁴

The coefficient of viscosity varies with the temperature. Poiseuille shows the general relation to be as follows:

$$N_t = \frac{N_o}{(1 + \alpha t + \beta t^2)}$$

Where N_o , α and β are constants for each liquid, t = temperature, and N_t the coefficient of viscosity at temperature t . For water $N_o = 0.017793$, $\alpha = 0.03580$, $\beta = 0.0002253$. For acetic acid $N_o = 0.016867$, $\alpha = 0.01826$, $\beta = 0.00008537$.

Slotte gives the relations as follows:

$$N_t = \frac{N_o}{(1 + \beta t)^n}$$

Where N_o , β and n are constants for each liquid.⁵

Still other empirical formulas showing the relation between coefficient of viscosity and temperature are in existence. Some of the constants apply only over limited ranges of temperature. Fig. 6 illustrates the effect of change in temperature upon the flow of water as computed by Poiseuille's rule given above. This shows that change in temperature has a very marked effect on the flow of liquids through porous masses, and is therefore of great importance in filtration.

Of the two types of flow there can be no doubt of the fact that the flow through a filter cake follows that of the non-sinuous or capillary type. This is indicated from the test by the behavior of the flow with respect to pressure.

Considerable investigation has been carried on in the past relative to the flow of water through porous masses

under the subject of underground flow. Darcy* in 1856 showed that the flow of water through soil varied as follows:

$$v = k \frac{p}{n}$$

Where v = vel. of ground water,
 p = pressure at end of soil column,
 n = length of column.
 k = a constant for different soils.

Hazen† in 1892 showed that:

$$v = cd^h \frac{h}{e} (0.70 - 0.03t)$$

Where v = vel. of flow,
 d = effective diameter of grain of sand,
 t = temperature,
 h = loss of head,
 e = thickness of sand,
 c = a constant.

Slichter* in 1897 showed that:

$$q = [1.0094] \frac{pd^2s}{\mu hk}$$

Where q = quantity in c.c.,

p = difference in pressure at ends of cylinder in centimeters at 4 deg. C.

d = diameter of soil grains in centimeters,

s = area of cross-section of the cylinder in square centimeters,

h = height of the column of sand in centimeters,

μ = coefficient of viscosity of the fluid,

k = a constant from Table II,

[1.0094] = the logarithm of a factor.

Table II is not here given, as the form of the equation is not affected thereby.

Franklin Kiram King* in a paper entitled "Principles and Conditions of the Movements of Ground Water," gave the results of a large number of tests showing the rate of flow of water through various porous mediums. In all cases the rate of flow varied approximately as the first power of the pressure.

All of these citations serve to verify the results of the test of the flow through a filter cake, and substantiate the conclusions already reached that the flow through a filter cake varies as the first power of the pressure.

EFFECT OF THICKNESS OF CAKE ON RATE OF FLOW

The effect on the rate of flow when the thickness of cake is varied, all other conditions being constant, can be inferred from Poiseuille's formula for capillary flow. This would indicate that the rate of flow varies inversely as the first power of the thickness. Darcy, Hazen, and Slichter have shown that this is true as far as flow through earth, sand and other porous mediums is concerned. It is safe to assume this is so as regards filter cakes also, as the thickness of cake corresponds to the length of tube in Poiseuille's formula.

At this point it is not practical to verify this assumption by actual test in a filter press, because the mathematical tools which will be disclosed later are not yet available. At first thought it would seem as though a test could be made to prove this statement by depositing a cake of a certain thickness and determining its rate of flow and then building up the cake to twice its original thickness and comparing its rate of flow with the first. This is not as simple as it seems, however, as, while it may be practical to deposit two cakes having a

thickness ratio of 1 to 2, it is quite another thing to secure two cakes having a resistance ratio of 1 to 2, because of the equivalent cake thickness of the cloth or filter base, and the effect upon the average thickness due to the grooves in the filter plate or filter support.

Later it will be shown how the above effects can be eliminated by mathematical means, but for the present the proposition that the rate of flow through a filter cake varies directly as the first power of the pressure and inversely as the first power of the thickness must be accepted as true.

PERMEABILITY

The above laws apply to flow of liquids through porous masses in general. To make the laws apply to a particular porous mass, another factor must be introduced. The writer can vouch for the fact that the flow through a 1-in. cake of Fuller's earth is quite different in amount from that obtained through a 1-in. cake of kieselguhr under similar conditions. If, however, the rate of flow under known conditions for each of the above substances be ascertained, the rate of flow under any other set of conditions for each one can be deduced from the general laws.

The factor which determines the rate of flow under known conditions may be called the permeability of the substance under those conditions. In order to place the permeabilities of different substances on a comparative basis it is necessary that the permeabilities be given for the same set of conditions. In other words, when the permeability of a certain porous mass is given, it should be understood that the value is that corresponding to a standard set of conditions—the same set to which all other permeabilities are referred.

The most convenient set of conditions to use as a standard in determining the permeability of porous masses are those which have values of unity. The permeability of a given substance may therefore be defined by the rate of flow through a cake 1-in. thick over an area of 1 sq. ft. when the pressure is 1 lb. per square inch. This greatly facilitates the reduction to flow under other conditions, it only being necessary to multiply the standard permeability of the substance by the area and pressure and divide by the thickness to obtain the new flow.

UNIT OF PERMEABILITY

A porous mass is said to have a permeability of one when unit pressure produces unit flow through unit thickness over unit area under standard conditions of temperature. In English units a porous mass is said to have a permeability of one when a pressure of 1 lb. per square inch produces a flow of 1 gal. per hour through a thickness of 1 in. over 1 sq. ft. of area at 68 deg. Fahr.

UNIT RESISTANCE

The reciprocal of the permeability of a porous mass is its resistance. It is easy to see that the resistance to flow of a porous mass varies inversely as its permeability. This being so, unit resistance may be arbitrarily defined as that resistance which a porous mass of unit permeability has. This unit is as yet unnamed.

EQUATION FOR FLOW THROUGH A POROUS MASS

The law governing the flow of liquids through a porous mass may now be expressed as follows:

$$\frac{dQ}{dt} = \frac{P}{R + t} \quad \text{..... (A)}$$

Where $\frac{dQ}{dt}$ = rate of flow of liquid with respect to time,

P = pressure of mixture,

R = resistance of material,

t = thickness of material.

Second Process—Building Up of Cake

There are two things which determine what the thickness of cake produced by a given quantity of a mixture of a solid and a liquid shall be. These are, first, the cake-forming ability of the mixture, and, second, the per cent of solids in the mixture.

CAKE-FORMING ABILITY OF A MIXTURE

Mixtures of various substances do not necessarily have the same cake-forming abilities. For instance, 5 gal. of a 2 per cent by weight mixture of kieselguhr and water will, when filtered through 1 sq. ft. of filtering area, produce a cake much thicker than would 5 gal. of a 2 per cent by weight mixture of Fuller's earth and water when filtered through the same area.

RATE OF DEPOSITION

The cake-forming ability of a substance when mixed with a liquid may be called the rate of deposition of that substance. A substance is said to have a rate of deposition or a cake-forming ability of one when, under standard temperature conditions, a 1 per cent mixture of the substance with water produces a flow of 1 gal. per hour over an area of 1 sq. ft. when the pressure is 1 lb. per square inch. This unit is also unnamed.

All other things being equal, the thickness of cake produced varies inversely as the rate of deposition. That is to say, having equal quantities of mixtures of the same proportions, but of different kinds of solids, that one requiring the greatest amount of mixture to produce a 1-in. cake will, of course, form the thinnest cake over the same area.

PER CENT OF SOLIDS

If a given quantity of a mixture of a solid and a liquid produces a cake of a certain thickness over a square foot of filtering area, one may double the thickness of cake produced by doubling the amount of solids in the given mixture. In other words, the thickness of cake produced by a mixture varies directly as the per cent of solids therein.

LAWS GOVERNING THE BUILDING UP OF CAKE

The laws governing the thickness of cake may be stated as follows: The thickness per unit quantity of discharge varies inversely as the rate of deposition and directly as the per cent of solids. Expressed symbolically:

$$t = \frac{\%Q}{k} \dots \dots \dots (B)$$

Where t = thickness, % = per cent of solids, k = rate of deposition, Q = total quantity of discharge.

Fundamental Law of Filtration

Up to this point the two processes, flow through a porous mass and building up of cake, which constitute the phenomena of filtration, have each been investigated and their laws deduced. It now remains to combine these two sets of laws and thus derive the fundamental law of filtration.

The law of flow through a porous mass is as given in equation (A):

$$\frac{dQ}{dT} = \frac{P}{R_c}$$

In filtration the porous mass is composed of the deposited solids plus the filter base. If the resistance offered to flow by the filter base be designated by R_m , the rate of flow through the filtering medium would be:

$$\frac{dQ}{dT} = \frac{P}{R_c + R_m} \dots \dots \dots (C)$$

The law governing the building up of cake is given in equation (B):

FIG. 6—EFFECT OF TEMPERATURE UPON THE FLOW OF WATER THROUGH A POROUS MASS

$$t = \frac{\%Q}{K}$$

Substituting this value of t in C:

$$\frac{dQ}{dT} = \frac{R_c'Q}{K} + \frac{R_m}{P}$$

$$\text{or } dT = \frac{R_c'Q}{PK} dQ + \frac{R_m}{P} dQ \dots \dots \dots (D)$$

In the above $\frac{dQ}{dT}$ is the rate of flow of filtrate. If the expression is integrated there results the expression of which $\frac{dQ}{dT}$ is the rate of change of discharge, Q , with respect to time, T . Such an expression is nothing more than the equation of the curve showing the relation between Q and T . In other words, it is the time-discharge curve from a filter or the fundamental law of filtration.

Integrating D between corresponding values of T and Q :

$$\int_0^T dT = \frac{R_c'}{PK} \int_0^Q Q dQ + \frac{R_m}{P} \int_0^Q dQ$$

$$\text{or } T = \frac{R_c'Q^2}{2PK} + \frac{R_mQ}{P} \dots \dots \dots (E)$$

In order to determine the value of Q alone, multiply both sides of E by $\frac{2PK}{R_c'}$ and add to both sides $\left(\frac{KR_m}{R_c'}\right)^2$.

This reduces E to:

$$Q = \sqrt{\frac{2PKT}{R_c'} + \left(\frac{KR_m}{R_c'}\right)^2} - \frac{KR_m}{R_c'} \dots \dots \dots (F)$$

Which is the fundamental law of filtration under standard conditions of temperature.

EFFECT OF TEMPERATURE

Temperature of a liquid effects its viscosity, and, as shown by Poiseuille's law, the rate of capillary flow is greatly influenced thereby.

To take this effect into consideration in the fundamental equation (F) it is only necessary to multiply the expression for Q by the amount representing the viscosity for the liquid under standard conditions and divide it by an expression giving the coefficient of viscosity for any other temperature. This must be so, because of the fact that the velocity of capillary flow

and therefore Q varies inversely as the coefficient of viscosity.

If Poiseuille's formula for relation between coefficient of viscosity and the temperature be used fundamental equation (E) becomes:

$$Q = \left[\sqrt{\frac{2PKT}{R'_c}} + \left(\frac{KK_m}{R'_c} \right)^2 - \frac{KK_m}{R'_c} \right] \frac{N_s}{1 + \alpha t_i + \beta t_i^2} \dots G$$

Where:

N_s = Coefficient of viscosity under standard conditions of temperature, say 68° F and $\frac{N_o}{1 + \alpha t_i + \beta t_i^2}$

Poiseuille's expression for the coefficient of viscosity at temperature t_i .

If the values for N_o , α and β at 20 deg. C. for water be inserted in G , the fundamental equation becomes:

$$Q = \left[\sqrt{\frac{2PKT}{R'_c}} + \left(\frac{KK_m}{R'_c} \right)^2 - \frac{KK_m}{R'_c} \right] \left(.556 + .0199t_i + .0001193t_i^2 \right)$$

Summarizing, it can be seen that filtration depends upon the following seven factors:

- P , the pressure
- T , the time of filtering
- K , the rate of deposition of the mixture
- R , the resistance of the material
- $\%$, the per cent of solids in the mixture
- R_m , the resistance of the filter base
- t_i , the temperature of the mixture

Two other factors may be added to this list, one, a factor modifying P , the pressure to allow for the squeezing together of non-rigid solids as the pressure increases, and another to take care of the influence of gravity through the agency of settling or sedimentation.

At first consideration it would appear as though the fundamental equation were too complicated to admit of practical use. Such, however, is actually not the case. It will subsequently be shown how this equation expressing the fundamental laws of filtration can be applied in the solution of practical filtration problems.

Batavia, Ill.

H. R. Conklin, Joplin, Mo., has issued an attractive little booklet describing the Conklin agitator, Conklin directed thickener, and Conklin bag filter.

Hydrostatic Instruments.—The Scientific Materials Company, Pittsburgh, Pa., has issued Efficiency Instrument Bulletin No. 4, describing various types of hydrostatic pressure and draft indicators and recorders. These instruments were formerly made in Germany, and are now made by this company.

Bromine.—The production of bromine in 1915 was 855,857 lb., valued at \$856,307, an increase of 278,866 lb. in quantity and of \$653,213 in value, according to the U. S. Geological Survey. The high price of bromine during 1915 and the first five months of 1916 was due, in part at least, to an unprecedentedly large demand from abroad. Bromine is made in connection with the manufacture of salt in the Saginaw Valley in Michigan, in the Ohio Valley in Ohio and West Virginia, and in the Kanawha Valley in West Virginia. In Michigan bromine has been marketed in the form of fine chemicals, but as a result of the great increase in demand caused by the war in Europe a large quantity is now being marketed as bromine itself. The bromine produced along the Ohio River, where salt and bromine occur naturally and where there is cheap rail and water transportation and an abundance of cheap coal and gas, has in part been exported to be made into fine chemicals. Here is an opportunity for the American chemist which should not be neglected.

Some Zinc-Lead Mills of California and Nevada

BY LEROY A. PALMER

It was only a few years ago that a zinc-lead ore presented a problem to the miner that he was unable to solve and that left him worse off than with a straight ore of either metal. Now, thanks to the advance made in the science of concentration, such an ore is no longer a disadvantage and may be so treated that all of the constituents yield a return to the operator.

In the following, brief mention will be made of three mills. Detailed description is not attempted for the reason that none of them involves any new principle, unless we except flotation, but all depend on the fundamentals of concentration.

The Needles Concentrator

The concentrator at Needles, Cal., Fig. 1, is one of the many plants of the United States Smelting Co. and follows the same general lines that this company first worked out successfully at Midvale, Utah. The ores treated are from the company's mine at Chloride, Ariz., and consist of galena, sphalerite, arsenopyrite and pyrite in a quartz gangue with some lime.

The ore is delivered at the mill in standard gauge, side-dump cars, which run onto a low trestle and are dumped to platforms beneath, Fig. 2. From these platforms the ore is shoveled to half-yard cars and teamed to a small bin below the ground level, from which it is delivered to a 30-in. conveyor 123 ft. long, which runs on an angle of 18 deg. and thus elevates the ore 38 ft. and delivers it to a hopper-bottomed bin. It is fed from this bin by means of a sector gate over an inch grizzly to a 12-in. x 18-in. Blake crusher set to 1 in. and making 240 r.p.m.

The crusher and grizzly deliver to a 14-in. elevator which dumps to two 3-ft. by 8-ft. trommels with $\frac{3}{8}$ -in. punched screens. The trommel oversize goes to a set of 16-in. by 36-in. rolls, making 70 r.p.m. The roll product is re-elevated to the trommel and the screen undersize goes to a 16-in. conveyor. This conveyor is 56 ft. long on an angle of 18 deg., so that the ore is elevated 17 ft. and delivered to the mill storage bin. From this bin it is fed by a plunger to a wet elevator, which delivers it at the top of the mill to the head of the screen line.

EXTENDED SYSTEM OF JIGGING AND TABLE CONCENTRATION

The primary screen line consists of three pairs of trommels with wire screens of $\frac{1}{4}$ in., $\frac{1}{8}$ in. and 1/16-in. mesh. The oversize of the trommels goes to eight three-compartment jigs of Harz type with plungers braced by steel straps from the eccentric stems. No

FIG. 1. NEEDLES CONCENTRATOR

FIG. 2—UNLOADING ORE AT NEEDLES MILL

jig product is rejected. The first compartment makes a lead-iron concentrate, the second lead-iron-zinc middling, the third zinc concentrate, while zinc middling discharges over the tailboard.

All middlings from the two coarser jigs go to a slope-bottom dewatering tank, one side of which is at an angle of 45 deg. and a few inches higher than the other. Lying against this sloping side is a 36-in. wheel with curved blades along the circumference, by means of which the middlings are scraped over the upper edge, while the slime overflows the opposite lower edge, passing over a screen for the removal of chips and thence to a Callow tank.

The dewatered middlings go to a set of wet rolls and are then elevated to the secondary screen line consisting of $\frac{1}{2}$ and 1/16-in. trommels. The oversize of both trommels is reground in a set of rolls which discharges to an elevator and back to the secondary screen line. The undersize of the 1/16-in. trommel goes to a jig similar to the others.

The middlings of the finer jigs, together with the undersize of the last primary trommel, go to settling boxes whose overflow passes to Callow tanks. The underflow is reground in a 4-ft. by 15-ft. tube-mill making 28 r.p.m. The tube discharge goes to an elevator by which it is raised to the Callow tanks.

The underflow of the Callow tanks goes to a three-compartment Harz jig and the overflow is laundered to a modified Calumet classifier, which feeds 15 Wilfley tables. These tables make five products: lead-iron concentrate, zinc concentrate with a small percentage of iron-zinc middling, tailing and slime. The concentrates go to hopper-bottomed boxes with 6-in. discharge plugs by which they are loaded direct to half-yard cars. The middlings are retreated on eight Wilfley tables, which make the same products as the first set. The tailings are retreated on three 6-ft. Johnston vanners, which make zinc concentrates and tailings, and the slimes are treated on three Deister tables, which make the same products as the vanners.

FLOTATION OF ZINC-BEARING SLIME

The Deister tailings and some of the original slime, amounting altogether to 20 tons per eight-hour shift, are retreated in a flotation plant for the further recovery of the zinc. This consists of three Callow cells. The pulp is agitated under 7 to 8-lb. air pressure in a small Pachuca tank in which it is mixed with oil and acid. The consumption of these materials in treating 20 tons per shift is 250 lb. of sulphuric acid and 10 to 16 lb. of oil, consisting of 75 per cent creosote and 25 per cent pine oil. The feed is distributed between two cells, the tailings of which are pumped to a third cell. No finishing cells are used, but the concentrates are

run direct to two Oliver filters for dewatering. The product of the flotation plant is zinc concentrate.

The mill has a capacity of from 200 to 225 tons per day. The concentration ratio on all products is 1.8 to 1, with one ton of lead concentrate to 4.2 tons of crude and one ton of zinc concentrate to 3.5 tons of crude. The zinc extraction is from 70 to 73 per cent and the total extraction is in excess of 90 per cent.

Yellow Pine Mill

The 100-ton mill of the Yellow Pine Mining Co. at Good Springs, Nev., is, strictly speaking, a separator rather than a concentrator. The ore is a high-grade lead-zinc material, and in the treatment at this plant no rejection is made, all products of the mill being shipped.

The ore is hauled from the mine in narrow-gage cars and dumped to the mill bins. It consists principally of lead carbonate and zinc carbonate and silicate. Sulphides are almost entirely absent as evidenced by the fact that the smelter returns on the lead concentrates show only 2 or 3 per cent sulphur.

From the mill bin the ore is fed to a short conveyor, on which the larger pieces of waste are sorted out. This conveyor dumps over a 1-in. grizzly and the oversize goes to an 8-in. by 16-in. roll-jaw crusher. Grizzly and rock breaker both discharge to a chain elevator, which dumps to the fine-ore bin.

The fine ore is delivered by a shaking feeder to a set of 16-in. by 36-in. Cornish rolls set to $\frac{1}{4}$ in. These discharge to a wet elevator, which raises the ore to the top of the mill, where it passes successively over $\frac{1}{4}$ -in. and $\frac{1}{8}$ -in. Impact screens. The screen oversize is treated on two 2-compartment Harz jigs, which make lead concentrates from the bed and hutch of the first compartment and middlings through the second compartment and over the tailboard. The middlings from the coarse jig are returned to the first set of rolls and those from the finer jig to a second set, both of which discharge to the elevator and to the Impact screens.

The undersize of the second screen goes to a five-compartment Richard's classifier, which makes six products, each of which goes to an Overstrom table. The tables make only two products, lead and zinc concentrates. The lead goes to tubs and the zinc, with all slime to settling bins beneath the table floor. The lead is shoveled to small cars, the zinc is drawn off through gates and the slime overflows to ponds from which it is shoveled out and shipped when a sufficient amount accumulates.

Under this system an extended run of 16,136.3 tons of crude ore assaying 10.2 per cent lead, 31.8 per cent zinc and 5.4 oz. silver produced 1521.085 tons of lead concentrate averaging 53.2 per cent lead, 13.75 per cent zinc and 28.1 oz. silver; 11,260.65 tons of zinc concentrate assaying 33.2 per cent zinc, 4.4 per cent lead and 2.5 oz. silver, and 2173.0 tons of slime averaging 7.3 per cent lead, 35.1 per cent zinc and 4.0 oz. silver; 833.4 tons of waste was removed by sorting. During 1915 milling cost was \$1.53 per ton.

Anchor Mill

The Anchor mill is characteristic of several dry mills that have been installed in the Good Springs district recently and uses a Stebbins table for concentration.

The ore is fed from the bin over a 1-in. grizzly to an 8-in. by 12-in. Dodge crusher set to $\frac{3}{4}$ in. The grizzly and crusher product go to a set of 14-in. by 30-in. rolls set to $\frac{1}{8}$ in. The roll product is elevated to an 8-ft. trommel with 8-mesh ton-cap screen, the oversize of which returns to the rolls and the undersize goes without further classification to a No. 6 Stebbins table with a capacity of two tons per hour.

PNEUMATIC CONCENTRATING TABLES USED

There are three products from this table: dust, which is removed by a fan and stacked behind the mill, lead concentrate, and either zinc concentrate or tailing, according to whether a zinc-lead or a lead ore is being treated. The lead concentrate is run to a bin by a conveyor belt and a screw removes the tailing or zinc product to another bin to be loaded to cars and wasted or shipped as the case may be.

The Stebbins table is made in seven different sizes, the extreme capacity of the largest size being 12 tons

FIG. 3—ANCHOR MILL, GOODSPRING, NEV.

per hour. In general design and principle of action it is similar to the standard makes of riffle-deck water tables. The shape of the deck is similar to that of the Wilfley and it is provided with longitudinal riffles, all of which extend clear to the concentrate end.

The deck is of sheet metal with perforated slots which have a slanting lip over each so as to direct the air current through the ore layer at an angle instead of directly upwards. Beneath the deck is an air chamber into which a blower forces air, at a pressure varied to suit conditions, and from which it escapes through the slots in the deck. The table has a reciprocating motion and stratifies the ore as on a water table, simply using air as a medium instead of water.

All machinery—crusher, trommel, rolls, elevator and table—is tightly housed and the dust is drawn off by a 30-in. fan. While this ameliorates conditions, the mill is, at best, very dusty and employees wear respirators.

By this system a lead-zinc ore carrying 35 per cent lead and 24 per cent zinc is separated into a lead concentrate assaying 67 per cent and a zinc concentrate carrying 34 per cent zinc and 6 per cent lead.

On a straight lead ore the saving approximates 65 per cent. This saving appears low, but it should be borne in mind that at this mill the dust, which has about the same metal content as the original ore, is not treated and the process is comparable with a wet mill that does not treat its slimes.

San Francisco, Cal.

The Kansas Chemical Co., Hutchinson, Kan., has taken up water purification as a side line of its regular work. The development has been in charge of Leslie C. Hughes.

The American Alkali & Acid Co., Bradford, Pa., is planning an extension of its plant. The equipment at present being obtained for the manufacture of toluol, benzol, anthracene, naphthalene, creosote, phenol, hard pitch and ammonia.

Practical Methods for Testing Refractory Fire Brick*

BY C. E. NESBITT AND M. L. BELL

The use of refractory material in metallurgical operations is one which, as a rule, is given but very general consideration. The selection of a suitable refractory calls for a study, first, of the temperatures involved, and secondly, of the nature of the hot material and resulting slag to which the refractory will be exposed.

Refractories are generally used in form of bricks or blocks which are molded from materials in the plastic condition, then burned. The resulting product is a solid of sufficient mechanical strength to permit its use for various forms of construction.

The two most common raw materials for making refractory bricks are clay and a variety of silica called ganister. Other raw materials are gradually finding wider and more general use, but these two continue to be the important ones.

Clay and silica rock suitable for bricks are widely distributed, but nature has very largely determined their physical properties. Each of these materials has varying physical properties which may be taken advantage of and incorporated into the finished bricks, the quality of which is largely dependent on the methods employed in their manufacture.

In its simplest terms a furnace or heating chamber consists essentially of a shell of brick work sometimes bound together with a suitable framework of iron. Owing to various physical, chemical and mechanical operations which take place in the furnace, the refractory must meet certain demands to give a satisfactory life. No brick can be expected to be best in all physical properties, and it becomes necessary to select the brick which is best suited to withstand that particular condition imposed by the furnace. It may be that the brick will have to withstand the abrasive action of heavy, hard materials, the sudden fluctuation of temperature, the corrosive action of slag, or the action of load while at high temperatures. These and similar points should be considered, their relative importance determined, and the brick chosen should be the one best suited to resist that particular condition.

In the iron and steel industry the blast furnace is one of the most important types of furnaces. In simple terms it is a hollow steel cylinder, approximately 100 ft. high and some 28 to 30 ft. in diameter, lined with fire brick. In a furnace of 500-tons capacity about 1900 tons of ore, limestone and coke are used every 24 hours. These materials, often wet or frozen, are fed in at the top and fall on the materials already in the furnace or roll over against the walls. Since this material must pass slowly through the furnace, the wear of the lining is extremely heavy. The temperature at the top of a blast furnace is low, but as the charge descends the temperature increases until the fusion zone is reached. In this zone the hard material composing the charge becomes a pasty mass which ultimately is melted, and the brick work then has to withstand molten iron and slag rather than abrasion or impact.

No blast furnace is complete without its battery of stoves in which no metallurgical operations take place. The object of the stove is to absorb heat rapidly and then as quickly give it up. Here a brick must withstand sudden thermal changes, abrasion, slagging, due to the dust carried by the burning gas, and possess good heat-absorbing qualities.

In one of the processes of converting pig iron into steel a basic open-hearth furnace is used. This furnace

*A paper presented at the Atlantic City meeting, June, 1916, of the American Society for Testing Materials.

is built up largely of silica brick, although the hearth is made up of basic materials because of the basic character of the slag, while the regenerators are of fire brick. Silica bricks are very sensitive to thermal changes, but owing to their infusibility and their ability to withstand heavy loads when highly heated, they are used almost without exception in open-hearth practice. Any variation in manufacture of material which will tend to decrease their sensitiveness to heat changes, without sacrifice to their other good qualities, will directly increase the life of the furnace.

In soaking pits, heating furnaces, annealing furnaces, mixers, ladles, etc., the temperatures are not as high as in the open-hearth furnace; the brick work here has mainly to withstand the action of the molten metal, iron scale, or slag.

A general review of the conditions imposed on fire brick as used about iron and steel plants has pointed out two general conclusions: (1) the life of a furnace is determined by the life of its brick work, and (2) different furnaces demand different physical properties in the brick used.

DESCRIPTION OF TESTS

A great many investigators have attacked the problem of refractories, the work having been done mainly from the standpoint of the inherent physical properties of the raw materials. The results are of high technical excellence and have been of value. In the majority of cases, however, the tests have not been applicable to brick as received by the consumer. He could not go out to his stock, select several bricks and quickly determine their value for his particular purpose.

With this idea in mind each of the various conditions where fire brick are used was studied to determine the cause of failure. The next step was to imitate actual conditions of service in the laboratory. This meant that tests must be employed which were very severe, producing in a short time what in actual service might require months, or even years to accomplish. To test brick cold and say that the result of the cold test was a measure of the performance when hot did not seem justifiable. Another point was to make the tests such that the work could be done on the brick as received, and not on bricks prepared for the test.

In the study of service conditions, attention was first

FIG. 1 IMPACT TESTS, ILLUSTRATING CHARACTERISTIC FRACTURES

directed to the top of the blast furnace. The average temperature at the top is about 260° C. The charging of a furnace is a nearly continuous operation, the material charged falling on the large bell, which, when lowered allows the material, often wet or frozen, to slide off the bell and strike the walls of the furnace. Immediately the charge starts slipping and grinding its way slowly downward past the brick in the wall. These

conditions required tests that would imitate impact, abrasion and spalling.

Impact Test.—An impact test was first considered. The rattler and other similar tests were studied, but it was finally decided that some kind of a drop test would be the most practical, and would most nearly approach service conditions. After trying many shapes and sizes of falling weights it was finally decided to use a steel

FIG. 2—ABRASION TESTS, SHOWING DIFFERENCE IN DEPTHS OF CUTS IN UPPER BRICK

ball 2½ in. in diameter. The brick was heated to 260° C. and the ball allowed to drop on the end of the brick from a height of 2 in., then 4 in. and so on, until the brick broke. The height to which it was necessary to raise the ball to cause fracture of the brick represents a particular quality, namely, resistance to impact.

The comparative strengths of brick to resist impact at ordinary temperatures and at slightly elevated temperatures is interesting. A brick heated to 260° C. and tested was 20 per cent weaker than a brick of the same brand tested at 20° C., and 40 per cent weaker when tested at 540° C. (Fig. 1).

Abrasion Test.—In developing an abrasion test it was

FIG. 3—SLAG PENETRATION AND ABRASION ON SILICA BRICK—PORTION OF AN 18-IN BULKHEAD

found that others had abraded brick in the cold by means of an emery wheel. This idea was modified so as to test the brick while hot. A temperature of 260° C. was adopted for top-wall and pipe brick, and 1350° C. for all others. The reason for choosing 1350° C. for the high temperature was that (1) it is a comparatively easy temperature to reach with a test furnace, and (2) while it might not represent the highest temperature in the

furnace, it is above the melting point of cast iron, and is applicable to all high-temperature furnaces used about iron and steel plants.

The brick to be tested was heated to 1350° C. and then pressed against a carborundum wheel, pressure and time being constant. When the brick became cold the depth of cut was measured and the result reported as linear inches abraded in 5 minutes. This test developed the interesting fact that bricks are not always the same at both ends, for it was found that sometimes there may be 10 to 20 times as much abrasion at one end as the other (Figs. 2, 3, 4 and 5).

Spalling Test.—Spalling was next studied. In brick work such a condition is usually the result of thermal changes, often accelerated by mechanical pinching. In actual service only one surface, generally the end or side of the brick, is exposed to the direct action of heat.

After trying various tests it was decided to place the brick to be tested in the wall of the furnace so that only one end was exposed. The testing temperature was

confined by the use of kaolin rings, but both tests were unsatisfactory. To confine a comparatively large portion of slag to any one portion of the brick it became necessary to drill a cavity in the brick and place the slag therein. Experiments were made to determine the effect of fineness of the slag, time of exposure to heat, and the effect of destroying the surface texture by drilling. To measure the slag penetration the brick is cut through the pockets of the slag and the area of brick penetrated by the slag measured with a planimeter (Figs. 8, 9 and 10).

Compression Test.—The ability of brick work to stand up under loads when highly heated is of great importance. A comparative test consisting of a modified Brinell ball test was used by heating the brick to 1350° C., removing from the furnace and then forcing a 2½-in. steel ball into the brick under a pressure of 1600 lb. The depth of the impression was then measured when cold (Figs. 11 and 12).

Expansion, Contraction and Fusibility.—These are important qualities of fire brick. For these tests the

FIG. 4—VERTICAL LINES OF EROSION ON A BLAST FURNACE AFTER SIX YEARS' SERVICE—UNIFORM WEARING

NOTE.—The letters E, A, etc., represent vertical sections taken on the diameters shown in the plan; the figures 1, 2, 3, etc., shown at the left and right, designate the horizontal sections, which are shown in Fig. 5. The figures on the outside of the vertical sections represent the thickness of the brick lining remaining at these points.

1350° C., and after a series of experiments as to the most satisfactory time for heating, one hour was decided upon, with 25 minutes' cooling in a blast of air. To produce a measurable spall at least 30 operations of heating and cooling were required. This was too long, and it was decided to increase the severity of the test by cooling in water for 3 minutes, and so hasten the spalling. A series of tests determined that cooling in water was three times as effective as air cooling. The number of operations was accordingly cut down to ten. The amount of spalling is reported as the percentage loss in weight. This test applies only to fire brick (Figs. 6 and 7).

Slagging Test.—The failure of brick work due to the corrosive action of slags is more prevalent than any other cause. Not only is the slag action marked in blast furnaces but also in open hearths, cupolas, and heating furnaces, and to a lesser degree in mixers, ladles, fireboxes, etc.

During the development of a slag test the slag was first placed on the surface of the brick. It was next

usual methods were followed, and they need not be mentioned further at present (Figs. 13 and 14).

RESULTS OF TESTS

As a result of a large number of tests following the methods which have been outlined, it was found that fire bricks tended to group themselves according to density. In general, bricks of high density, all other factors being equal, have the most desirable qualities, namely, least abrasion, good resistance to slag and least compression. Spalling is very slightly increased, but not to a dangerous extent if bricks are not over-burned.

As a measure of density, the apparent specific gravity is used—obtained by weighing and measuring the brick and not by suspension, as is usually done. Results show that various makes of brick have characteristic values for apparent specific gravity and that the method of manufacture greatly influences the density. A series of preliminary experiments had shown the importance of pressure and moisture in producing a dense brick, and this test was followed up by a more elaborate series. A

TABLE I—RESULTS OF TESTS ON FIRE BRICK OF VARYING MOISTURE CONTENT

Properties Considered	PERCENTAGE OF MOISTURE						
	4	6	7	8.5	10	12	
Apparent specific gravity	2.11	2.17	2.19	2.16	2.10	2.06	
Compression at 1350 deg. C., depth of impression, in.	0.49	0.44	0.43	0.51	0.53	0.57	
Expansion per foot of length at 1350 deg. C., in.	0.064	0.064	0.045	0.045	0.049	0.050	
Impact at 260 deg. C., height of drop, in.	18	33	45	35	31	30	
Abrasion at 1350 deg. C., in five minutes, in.	0.024	0.008	0.012	0.016	0.028	0.020	
Blast-furnace slag, sq. in.	0.37	0.30	0.24	0.28	0.43	0.36	
Open-hearth slag, sq. in.	0.82	0.48	0.58	0.66	0.66	0.74	
Heating-furnace slag, sq. in.	1.65	0.35	0.29	0.42	0.42	1.26	

standard fire-clay mixture was used, in which the moisture was varied from 4 to 12 per cent, and all bricks were pressed at 2000 lb. per sq. in., then burned in a regular kiln. Results of tests applied on this series are shown in Table I and Fig. 15.

TABLE II—RESULTS OF TESTS ON A HIGH-PRESSURE, LOW-MOISTURE BRICK AND A HAND-MADE, REPPRESSED, ORDINARY-MOISTURE BRICK

Properties Considered	KIND OF BRICK	
	Pressure of 1500 Lb. per Sq. In., Moisture, 7 per Cent	Hand Made, Repressed, Ordinary Moisture
Compression at 1350 deg. C., depth of impression, in.	0.29	0.55
Expansion per foot of length at 1350 deg. C., in.	0.062	0.059
Impact at 260 deg. C., height of drop, in.	45	28
Abrasion at 1350 deg. C., in five minutes, in.	0.02	0.04
Spalling, loss, per cent.	9.4	10.6
Slag penetration, (Blast-furnace slag, sq. in.)	0.27	0.56
(Heating-furnace slag, sq. in.)	0.26	0.67

Conclusions can only be drawn when all conditions except brick quality are the same.

FIG. 5—HORIZONTAL LINES OF EROSION ON A BLAST FURNACE AFTER SIX YEARS' SERVICE—UNIFORM WEARING

NOTE.—The letters at the ends of a diameter refer to the corresponding section indicated in the plan view of Fig. 4. The figures at the ends of a diameter indicate the thickness of the brick remaining at the ends of that diameter. For example: Horizontal section No. 1 shows thicknesses at the ends of the diameter EA equal to 36 and 40 in.; at the ends of diameter FB, 26 and 54 in., etc. These figures will also be found along the horizontal line of section No. 1, in Fig. 4.

Power-pressing a brick during manufacture up to 1500 lb. per sq. in. has been found to materially improve the quality of most fire brick; beyond that figure very little improvement is made. A comparison of tests on a high-pressure, low-moisture brick and a hand-made, repressed, ordinary-moisture brick, both brick of the same mixture, is given in Table II.

The laboratory methods suggested have been developed mainly with reference to bricks to be used in iron and steel plants. When modified they are applicable to almost any condition of service to which the bricks will be subjected. If a brick is to be used in a boiler setting, copper or lead smelter, calcining or roasting furnaces, the test should imitate these conditions, in order that the results be comparative. Conditions of service must be studied to learn what is demanded of a brick.

When a laboratory test has been developed it must be confirmed by actual service tests. To compare the life of two similar furnaces built of different materials, or even the same furnace built of different materials at different times, does not necessarily mean that the material showing the longest life is the better, since the operating conditions may have been decidedly different.

To derive the greatest benefit the consumer and manufacturer must work together. The manufacturer's interest must not cease with the shipment of his product. The consumer should provide all reasonable facilities for the manufacturer to study his product in actual service. It is only by such co-operation or exchange of information that the best results can be obtained. A more detailed description of apparatus and methods is appended.

APPENDIX

Methods of Testing Refractory Fire Brick¹

IMPACT TEST

Construction of Apparatus.—The machine for determining the resistance to impact consists of two vertical uprights 15 ft. high, supporting two vertical and parallel 1½-in. angle irons. The angle irons are placed so that their inclosed angles face each other and are braced 3½ in. apart measured from the inside of the

¹At the present time the machines and apparatus here described are in a state of development, and while they have been standardized for the test, the machines and methods themselves are not necessarily final.

angles so as to allow a ball $2\frac{1}{2}$ in. in diameter to fall freely between them, the sidewise movement of the ball not to exceed $\frac{1}{4}$ in. These angle irons are adjusted so that bricks of different heights may be placed under them, and are marked, beginning at the lower ends, so as to clearly designate successive heights of 2 in. The test specimen is placed directly below the angle irons on a steel block of sufficient size to give a solid foundation. The upper face of the block is perfectly smooth and at

FIG. 6—CHARACTERISTIC SPALLING-TEST SPECIMENS

right angles to the angle irons. The block is $6\frac{1}{2}$ by 15 by 12 in., and weighs 332 lb. The falling weight is a steel ball $2\frac{1}{2}$ in. in diameter weighing 2.34 lb.

Operation of Test.—The brick to be tested is first carefully inspected, and, if necessary, ground on a carborundum wheel so that it sets firmly on one of its ends. On the other end of the brick the diagonals are then drawn to locate the center. The brick is now placed in a cold furnace and heated at a uniform rate from atmospheric temperature to 260° C., so that at least one hour is required to reach the final temperature. The final temperature (260° C.) is maintained for not less than three hours.

The brick is now ready for the test and is placed on

FIG. 7—SPALLING IN ROOF OF AIR FLUE OF OPEN-HEARTH FURNACE

(Note similarity between actual and test spalling)

the steel block, so that the ball between the angle irons touches the brick at its marked center. Iron blocks are placed around the brick until they are nearly level with the top of it, to prevent sidewise movement, but the brick is not wedged. The ball is now dropped from a pair of tongs on the end of the brick at successively increasing heights of 2 in. until the brick fractures. Any fracture radiating 1 in. or more from the point of contact of the ball is considered a fracture, and the distance in inches of the last drop is the result of the test. If the ball is allowed to drop again from the last height the brick

FIG. 8—CHARACTERISTIC SLAG-TEST SPECIMENS

gives off a dead or broken sound. The clear ring of a sound brick has disappeared.

COMPRESSION TEST

Construction of Apparatus.—The machine for determining the resistance to compression is a modified Brinell ball testing machine and consists of a 4-in. I-beam 10 ft. long and weighing 75 lb., so arranged as to act as a second-class lever arm; that is, one end is the fulcrum and at the other end the weight is applied so as to produce the compression on the brick placed 6 in. from the fulcrum. All bearings are knife-edged. The fulcrum end of the bar is mounted between two vertical uprights, 10-in. channel irons and so arranged that the height of the fulcrum may be adjusted by a hand wheel to suit bricks of varying thickness. Six inches from the fulcrum towards the weighted end of the bar a spherical

FIG. 9—CHECKERS IN GAS CHAMBER OF OPEN-HEARTH FURNACE, SHOWING SLAGGING

depression marks the location of the ball. The ball is a steel ball $2\frac{1}{2}$ in. in diameter weighing 2.34 lb. The brick to be tested rests on a solid foundation directly below the depression. The bar alone produces a pressure of 850 lb. on the ball, and the balance of the weight is added at a uniform rate of 25 lb. per second by means of dry sand, which flows from a hopper into a bucket at-

FIG. 10—INDIVIDUAL CHECKERS FROM GAS CHAMBER OF OPEN-HEARTH FURNACE, SHOWING SLAG PENETRATION

tached to the end of the bar. Bar and sand together produce a total load on the ball of 1600 lb.

Operation of Test.—The brick to be tested is placed in a cold furnace and heated slowly to 1350° C. The heating as a convenience is done over night at a uniform rate not to exceed 260° C. per hour. Total time of heating should in no case be less than 6 hours. The brick before testing should be maintained at 1350° C. for not less than 3 hours.

The brick is now removed from the furnace and placed flat on the foundation beneath the bar, and the bar lowered so that when the ball is in position in the depression it is also in contact with the center of the upper surface of the brick. The weighted end of the bar is then gently released and the flow of sand immediately started. The time required to remove the brick from the furnace and apply the load is less than one minute. The pressure is maintained for five minutes, starting from the time the bar is released. The brick is then removed from the machine and allowed to cool. When cold the depth of penetration produced by the ball is measured by placing centrally over the depression a flat rectangular plate $3\frac{1}{2}$ in. sq. ($\frac{1}{4}$ in. thick), at the center of which is mounted at right angles to it a Brown & Sharpe micrometer depth gage. The lower end of the stem of the micrometer is rounded so that it has the same radius as the $2\frac{1}{2}$ -in. ball. The depth at the center of the depression is measured to 0.001 in.

ABRASION TEST

Construction of Apparatus.—The abrasion testing machine consists of a carborundum wheel mounted on a suitable stand and revolving vertically. In front of the wheel and resting on the stand is an L-shaped plate $6\frac{1}{2}$ by 16 by $\frac{1}{4}$ in. resting on roller bearings and forced

FIG. 11—CHARACTERISTIC COMPRESSION-TEST SPECIMENS, SHOWING DEPTH OF BALL AND CORRESPONDING IMPRESSIONS

towards the wheel by means of a right-angle lever arm, and suspended weights. The upper surface of this plate is $1\frac{1}{4}$ in. below the horizontal radial line drawn from the center of wheel. All points of contact on the lever arm are knife-edged and friction is reduced to a minimum. The carborundum wheel is 18 in. in diameter, has a 2-in. face and $1\frac{1}{2}$ -in. center hole, and is purchased from the Carborundum Company, grit 16; grade J; bond G-5. The wheel is motor driven and has a surface speed of 1640 ft. per minute and is to be redressed when the corners wear away $\frac{1}{4}$ in. of their original radius, or as soon as the face ceases to be at right angles to the side of the wheel. The pressure of the brick against the

FIG. 12—SPALLING, ACCELERATED BY COMPRESSION, OF ENTIRE CORNER OF AIR FLUE IN OPEN-HEARTH FURNACE

wheel is 10 lb. per sq. in. of brick in contact with the wheel, excluding the pressure required to move the brick.

Operation of Test.—The brick before testing is ground cold to a uniform thickness of 2.35 in. for $2\frac{1}{2}$ in. brick, and for 2.80 in. for a 3-in. brick, and the ends ground so that the testing wheel cuts through this thickness. The depth of this preliminary cut is measured at its center, using the rectangular plate described under the compression test. The brick prepared for test is heated

FIG. 13—CHARACTERISTIC SOFTENING-TEST SPECIMENS

the same as under the compression test, except in the case of top-wall and pipe brick, which are heated the same as for the impact test.

The brick is then removed from the furnace, placed flat on the plate in front of the wheel so that the wheel enters the preliminary cut, and is then abraded for five minutes. The time is taken with a stop-watch. In the case of soft brick, which abrade very rapidly, the test is run for a fraction of the period, and then calculated

to the five-minute period. The brick is now returned to the furnace and reheated for not less than one hour. The test is then repeated on the other end of the brick. When cold the depth of cut on both ends is measured, and the difference between the preliminary and the final cuts is the result reported.

SPALLING TEST

Operation of Test.—Preparatory to the test the fur-

minutes. The bricks are then removed and allowed to dry for three minutes in air. To indicate three-minute periods a stop-watch is used. The bricks are then placed in the doorway of the furnace as before, and the operation repeated for a total number of ten times. The bricks are now dried at 100° C. for at least five hours, and all particles which can be easily broken off with the fingers removed. The bricks are then weighed and the percentage of loss calculated from the original weight.

FIG. 15—INFLUENCE OF WATER USED IN MANUFACTURE ON PHYSICAL PROPERTIES OF FIRE BRICK

nace is heated to 1350° C. and held at this temperature for about one hour. The bricks to be tested are dried at 100° C. for at least five hours, weighed, and then placed in the doorway of the furnace, their ends flush with the inside of the wall. In case a sufficient number of bricks are not being tested to entirely fill the doorway, the remainder of the space is filled in with other bricks to insure heating the ends only. The bricks are now heated for one hour and plunged separately into 2 gal. of water at 20° C. to a depth of 4 in. and held there for three

FIG. 14—GAS AND AIR PORTS INSIDE OPEN-HEARTH FURNACE
(Note slagged condition of walls and roof, and total disappearance of brick around water cooler in foreground.)

SLAGGING TEST

Operation of Test.—In preparing the sample for the slagging test, the 9 by 4½-in. unbranded side of the brick is bisected by a line across the narrow dimension and diagonals drawn on each half. At each intersection of the diagonals a circular cavity is drilled 2½ in. in diameter and ½ in. deep at the sides. The drills are 5/16 in. thick and 2½ in. wide, measured diagonally across opposite corners, while the point of the drill includes an angle of 150 deg. A template is made of 3 16-in. sheet steel to insure that all drills are ground properly. To insure a standard depth of cavity, two in-

FIG. 16—AXIS ALONG WHICH MEASUREMENTS ARE TAKEN IN DETERMINING THE SIZE OF A BRICK

verted U-shaped pieces of metal are clamped to each drill when in use and adjusted so that drill cannot enter the hole more than $\frac{1}{2}$ in., measured on the side of the drill. The cross-section of the cavity passing through the deepest point has an area of 1.7 sq. in., and is checked up for size and depth by a template. The pressure used in drilling must not be so severe as to partially crack the brick.

After the cavities have been drilled and cleaned of loose material the bricks are placed level in a cold furnace and heated as in the compression test. When 1350° C. is reached 35 g. of standard blast-furnace slag are placed, by means of a long rod with a spoon-shaped end, in one cavity, and 35 g. of standard heating-furnace slag in the other cavity. The slags used shall have approximately the following analysis and melting points:

	Blast-Furnace Slag	Heating-Furnace Slag
Silica (SiO ₂), per cent.	38.0	35.0
Iron (Fe), per cent.	1.5	44.0
Manganese (Mn), per cent.	1.0	0.5
Alumina (Al ₂ O ₃), per cent.	14.5	6.0
Lime (CaO), per cent.	42.0	1.5
Magnesia (MgO), per cent.	2-0	0.5
Sulphur (S), per cent.	1.0	
Melting point, deg. Cent.	1260	1260

The fineness of the slag is such as to pass a 40-mesh sieve. The bricks are kept at a temperature of 1350° C. for two hours after the slag is added, at the end of which time the furnace is allowed to cool, or the bricks may be removed from the furnace and allowed to cool in air. The bricks when cold are sawed lengthwise at a right angle to the unbranded side, so that one side of the cutting wheel cuts through the center of the drilled cavity, and this area of slag penetration, together with the cavity, is measured with a planimeter. The area of the original cavity is subtracted, giving the result in square inches of slag penetration. The wheel used for sawing the brick is a carborundum wheel 12 in. in diameter; $\frac{1}{8}$ in. thick; $1\frac{1}{2}$ -in. center hole; grit 16; bond NCH.

SOFTENING TEST

Operation of Test.—The test specimens for determining the softening temperature are cut by means of the saw used in slagging test from the corner of the brick, in the shape of a triangular pyramid similar to that of a Seger cone. They are 3 in. high, and the base should not be less than 1 in. on the side. The test specimen, together with a series of Seger cones, is set in some good refractory material which will not flux with the sample. The series of cones used includes numbers both below and above the cone at which the sample is supposed to soften. The whole is placed in a gas-fired furnace and heated at a uniform rate, not to exceed 600° C. per hour. The softening temperature is considered that at which the specimen either bends double, sags, or puffs out of shape and is determined by Seger cones.

EXPANSION AND CONTRACTION

Construction of Apparatus.—The machine used for the measurement of expansion and contraction consists of a micrometer mounted on a steel post, which in turn is mounted on a steel plate 24 by 6 by $\frac{1}{2}$ in. To the stem of the micrometer is fastened a steel disk 1 in. in diameter and $\frac{1}{8}$ in. thick. In line with the micrometer is a second steel post on which is mounted a $\frac{1}{4}$ -in. sliding steel rod with a similar circular disk, as with the micrometer. The rod can be adjusted so as to determine measurements up to 14 in. To insure that this rod is properly set, standard bars 3, 5, 9, 11 and 13 in. long are used.

Operation of Test.—In preparing the brick for the test

the ends of the brick are ground so as to be parallel to each other at right angles to the sides. The length is then measured cold. The brick is then heated as in the compression test—or as for the impact test in the case of top-wall and pile brick—removed from the furnace and measured hot. The removing from the furnace and measuring usually requires about 30 seconds. The result is calculated to inches per linear foot.

SIZE

Operation of Test.—The size is determined by the use of the micrometer described under expansion and contraction. All measurements are made while the brick is at atmospheric temperature. Small particles of sand, clay or foreign matter adhering to the brick are removed before measuring. The locations for taking the measurements are shown in Fig. 16. If the bricks are of a different size than a standard 9-in. brick, the measurements are made in the same way, but at a point of one-fourth of their respective dimensions.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Oxidation of Soluble Sulphides in Cyanide Solutions.—In the course of experimental work on leaching roasted ore with cyanide solution, H. R. EDMANDS gave attention to solutions foul with soluble sulphides and the oxidation of those compounds. His results are recorded in the April *Journal* of the Chamber of Mines of Western Australia. The general impression has been that soluble compounds were very unstable, disappearing on decantation from one vessel to another, if they are not already precipitated by the zinc always present in mill solutions. Results showed that their proneness to oxidation has been overestimated and that the presence or absence of protective alkalinity has little effect on their oxidation, but that soluble carbonates tend to hasten oxidation. A more effective oxidation occurs in the leaching vats where, after draining, a strong oxidizing effect is given by included air, assisted by the presence of ferric oxide.

Effect of Lead Salts in Cyanide Treatment.—The same author gives results of solvent activity tests, using various solutions on pure gold and roasted ore. For the pure gold tests he used a plate of metal of 9 sq. cm. total area, and agitated it for 16 hours in a stoppered bottle of 344 cc. capacity, with 200 cc. of the solution to be tested, thus leaving 144 cc. of air containing about 0.038 g. oxygen, or sufficient for the oxidation of 945.6 mg. gold. In addition the effect of adding lead acetate to solutions containing soluble sulphides was determined and from this it appears that if the precipitated sulphide be removed by filtration a considerable increase in solvent activity ensues, but that the presence of PbS renders solutions carrying any protective alkalinity almost incapable of dissolving gold, which power is only imperfectly restored by neutralizing the protective alkalinity.

Experiments made on the roasted ore showed that the addition of CaO improved extraction; adding lead acetate in addition to CaO gave a further improvement; but the best extractions were obtained by adding acetate and omitting lime, at a cost, however, of greater cyanide consumption.

It should be noted that in these tests no soluble sulphides were detected either before or after treatment.

Somewhat different results were obtained by two following tests, in which roasted ore was agitated with solution foul with soluble sulphides.

A. Solution contained 0.0036 per cent soluble sulphides in terms of K₂S, 8 lb. CaO added per ton ore, and excess air present.

	Residue
(1) Amount acetate added, twice that required to precipitate all K ₂ S.....	178. 6d.
(2) Acetate sufficient to precipitate all K ₂ S, no excess.....	108. 6d.
(3) No acetate used.....	88. 6d.

B. Solution contained 0.0023 per cent soluble sulphides, in terms of K₂S, no CaO added, but solution on already contained 0.019 per cent CaO.

	Residue
(1) Excess air present.....	158. 0d.
(2) No excess air, air excluded.....	308. 0d.
(3) Excess air, acetate to precipitate all sol. sulphides, but no excess.....	88. 0d.

Solutions off contained no protective alkalinity, and except No. 2 were free from K₂S.

It would appear that under these conditions, in a solution containing little or no protective alkali, the use of acetate in just sufficient quantity to precipitate soluble sulphides, is beneficial but may be injurious in the presence of much CaO, especially if the acetate be in excess.

Cement and Concrete

Tricalcic Silicate in Portland Cement.—According to a paper published by GEORGE A. RANKIN in the *Journal* of the Franklin Institute, the major constituents of Portland cement are tricalcic silicate, dicalcic silicate and tricalcic aluminate. Of these the compound tricalcic silicate is the one that hardens and develops the greatest strength within a reasonable time. While most important, this compound also is the one most difficulty formed, and comprises but 30 to 35 per cent of an average normal Portland cement. It may be said, therefore, that the essential process for the manufacture of Portland cement is the formation of this compound and that any improvement in the process which will increase the percentage of this constituent will add to the cementing value of the product. In order to determine the most economical process for producing this compound in higher percentages, it will be necessary to study the rate of its formation in a series of mixtures of various substances. It will be necessary also to determine the equilibrium relations of the compound at high temperatures in such mixtures. A scientific investigation of this kind will lead sooner to the discovery of the best composition than the empirical cut-and-try methods.

Specification for Concrete Aggregates.—Instead of specifying that concrete aggregates, especially sand, be of a certain fixed minimum standard of quality, which may not be attained in certain localities, it is proposed by C. M. CHAPMAN in *Engineering Record*, July 8, that the specifications shall read about as follows: "The materials used shall be of such quality and shall be used in such proportions, as to produce a concrete which shall show a compressive strength of 2500 (or 2000 or 1500) lb. per square inch at the age of 28 days, when tested according to standard methods." The author contends that specifications should be drawn to insure the production of suitable concrete if the aggregates are properly used and should permit of the use of local materials when they are capable of producing concrete of the required quality. It is better to specify the result required than to handicap the builder with specifications as to material which he cannot fulfill.

It is assumed, for instance, that for mass foundations and footings, retaining walls, abutments and similar service, a concrete of compressive strength of 1500 lb. per square inch at age 28 days is suitable. For reinforced walls and matts where stresses are moderate a compressive strength of 2000 lb. may be required,

while for reinforced floor slabs, beams, girders, columns, etc., a minimum compressive strength of 2500 lb. may be necessary. By specifying the results required and permitting the use of such materials as will produce these results when tested under specified standard conditions, it is possible not only to safeguard the products but to permit the use of locally available materials. In operating under such specifications it is important to test specimens of concrete produced on the job and check the quality of materials used so as to insure reasonable uniformity.

Distillation

Operation and Costs of an Eight-Effect Distilling Plant.—The number of bodies or effects in commercial distilling plants varies from one to twenty-four, this number having been proposed, although installations having more than eight are rare. In the *Journal* of the Engineers Club of Baltimore, June, 1916, FRANK T. LEILICH gives a description of an eight-effect salt-water distilling plant of the Lillie type. It is designed particularly for use in ice-making plants, bottling establishments and marine service.

The present tests were made on a plant installed in an isolated fortification where fuel is expensive and storage facilities limited. Diesel engine prime movers are employed and the boilers furnishing the steam for the distilling plant are fired with fuel oil. The plant was designed to meet specifications calling for 5000 gal. per day of distilled water. The average production was to be not less than 6 lb. for every 1177 B.t.u. of total heat above 32 deg. Fahr. contained in the steam supplied and a thirty-day demonstration was to be made.

The pressure ranges decided upon were 10 lb. gage to 24 in. vacuum. The shell and heads were made of cast iron, both heads being hinged, and the steam tubes were of copper. The plant was arranged to be operated with either half as a quadruple effect and both halves reversible.

During the preliminary tests the steam quality was determined by means of a throttling calorimeter. Later this instrument was rendered unserviceable by an accident, and as the contractor agreed to accept the test results on the assumption that the steam supplied contained no moisture, the damaged calorimeter was not replaced. The exhaust from the condenser pump and a condenser cooling water pump furnished nearly all of the steam required for octuple running. These pumps and the make-up passing through the reducing valve were supplied with steam at 90 to 100 lb. gage by two hoisting engine boilers.

During the first few weeks of running, the operation of the plant was not satisfactory, as the condenser pump proved to be too small and the performance of the apparatus was spasmodic. However, the purity of the distillate produced was as good as required by the specifications. Several sizes of pumps were tried before one suited to the service was secured. While experimenting with the pumps various modifications of the gas removal connections were tested out, but with the proper size of condenser pump the original connections were found to be most satisfactory. In addition to the pump and gas accumulation troubles, the removal of the condensation from the steam end No. 8, working with No. 1 hottest, was neither regular nor positive. This caused irregular discharge and reduced the rate of working, as the tubes in No. 8 would become flooded. In the opinion of the author both of the above difficulties can be traced primarily to the small pressure drop in the effects. In his opinion, a plant operating between the pressure ranges of 10 lb. gage and 24 in.

vacuum should not have more than six effects. When either half of the plant was operated quadruple, no trouble was experienced, which seems to substantiate the above view. After considerable experimenting, what might be termed an equalizer pipe running under the effects was installed connecting the condensation discharge at No. 8 with the condensation connection into the condenser. After the installation of this line, the pump removed the condensation from No. 8 as fast as it accumulated and the plant ran at a uniform rate.

The thirty-day run was started on Nov. 9, 1914, the plant being operated by three shifts of two men each. The operators were required to make hourly records of the readings of the various gages and thermometers connected with the apparatus.

When the apparatus was shut down at the end of the thirty-day run the heads were opened and the scale formations carefully examined. The tubes were coated with a substance resembling common salt, the coating being about as thick as an ordinary visiting card. Most of the coating could be scraped off with a small stick. The deposit was not analyzed, but a sample that was put into dilute hydrochloric acid was almost completely dissolved. After the completion of the thirty-day run, and without cleaning the tubes, several economy tests were made. The results of a few of these are summarized in Table I.

TABLE I

Test No.	Date	TIME		TIME		READINGS OF GAGES ON EFFECTS								Vae. Cond.	Lb. Dist. per Lb. of Steam*	GALLONS		Lb. Dist. per Lb. of Steam	Daily Rate, Gallons	Remarks
		Start, P.M.	Finish, P.M.	Reverse, P.M.	Min. Rnd.	1	2	3	4	5	6	7	8			Steam	Total Out-put

6	1 22 15	9 35	10 08							19.7°	11.5°	4.4°	1.8°	24.1°	5.2	36	186	5.2*	7600†	

*Effect of reversal not included.

†Calculated on a basis of 6 reversals per day, 24 hours of full capacity running.

After making several economy runs, it was found that the output per pound of steam depended considerably upon the care in operation, and individual results were difficult to reproduce.

During all tests the distillate was sampled at regular intervals. Grab samples of about 25 c.c. were taken and all samples taken during a test were poured into a clean bottle which was kept securely corked. The contents of the bottle were assumed to represent the average quality of the distillate produced during the run. The samples were tested for chlorine only. The results of the analysis of a few of the samples are given in Table II below.

Test No.	Date	TABLE II		Aver. of 4 determinations
		Operating (1915)	Aver. gr. of Cl per gal.	
1	Jan. 11	Octuple	.306	" " " "
2	Jan. 15	Octuple	.731	" " " "
3	Jan. 16	Quadruple	2.510	" " " "
4	Jan. 22	Octuple	.76	" " " "

These analyses are believed to be representative of what the apparatus will do when attended by a skillful operator. The men employed as operators during the test had no previous experience with the apparatus and worked under the supervision of the contractor's representative. After operating under these conditions for about four weeks two of the men could be depended upon to handle the plant satisfactorily. Reversing re-

quires considerable care in order to prevent "pulling over" salt water. Carrying the brine levels too high also results in a salty product. These levels are not maintained automatically, but with uniform supply pressures an experienced operator can readily find by trial the proper setting of the four-way feed cocks for continuous feeding of the apparatus.

The Lillie apparatus is especially adapted to installations where a supply of exhaust steam is available and where fuel costs require that the distillation be carried out with a minimum expenditure of heat. As regards scale formations, the Lillie plant will show to best advantage when the distillation is from sea water or other source approaching this in character. While a six or eight effect reversible plant is somewhat more complicated than the more common types of evaporators, experience has demonstrated that employees of average intelligence can, in a few weeks, become proficient in the operation of the apparatus. As usually built, the effects are arranged horizontally and hence require considerable floor space for the installation.

The cost of a plant will, of course, be dependent upon the capacity and other circumstances connected with the proposed installation. The plant described in this paper is for installation on a military post and hence the operating costs have but little commercial significance. Assuming, however, the equipment would be used com-

mercially the costs would probably be about as set forth in Table III below.

TABLE III—FIXED CHARGES AND OPERATING COSTS

A—Fixed charges (based on an investment of \$16,500 for eight-effect distilling plant complete with boilers and auxiliaries).	
Interest, 6%	\$390.00
Insurance and taxes, 1%	165.00
Depreciation, 5%	825.00
Total.....	\$1,380.00
B—Operating costs (based on operation for 300 days per year).	
Labor, one operator at \$60 monthly.....	\$720.00
Repairs and maintenance, estimated at 3% of first cost.....	495.00
Fuel—Coal at \$3.50 per ton (assumptions:—8 lbs. of steam per lb. of coal, 6 lbs. of distillate per lb. of steam, 9 hours daily operation at rate of 7,000 gals. in 24 hours, 12% allowance for steam used in warming up, leakage, etc.).....	270.00
Total.....	\$1,485.00
C—Operating costs based on operation for 300 days, 24 hours per day.	
Labor—Three operators at \$60 each monthly.....	\$2,160.00
Repairs and maintenance, estimated at 3% of first cost.....	495.00
Fuel—Coal at \$3.50 per ton (assumptions:—8 lbs. of steam per lb. of coal, 6 lbs. of distillate per lb. of steam, 7,000 gals. daily output, 8% allowance for steam used in warming up, leakage, etc.).....	690.00
Total.....	\$3,345.00
Summary:	
Total costs, (A) plus (B).....	\$2,865.00
Yearly output (300 days of 9 hours), gallons.....	787,000
Cost per gallon.....	.0044
Total costs, (A) plus (C).....	\$5,325.00
Yearly output (300 days of 24 hours), gallons.....	2,100,000
Cost per gallon.....	.0025

The above cost estimates are of necessity only rough approximations. The capital investment, it should be noted, includes the cost of boilers, etc., and is perhaps higher than it would be for an ordinary commercial plant. Operating costs do not include labor of a fireman, it being assumed that the increased load of the distilling plant could be handled without an increase in the fire-room force. This is a fair assumption, as the distilling plant attendants would have sufficient spare time to render service in other ways that would at least balance any fire-room labor charges.

Recent Chemical and Metallurgical Patents

Cyanides and Cyanamid

Production of Cyanogen Compounds.—An electric furnace process of producing cyanogen compounds and ammonia is patented by AXEL R. LINDBLAD, of Ludvika,

FIG. 1—CYANIDE AND AMMONIA FURNACE

Sweden. A cross-section of the furnace is shown in Fig. 1. In the manufacture of cyanides; potassium or sodium carbonate, or their hydroxides may be used. One of these is charged into the furnace through hopper section 8. Charcoal is fed in at 16, and nitrogen or a nitrogen containing gas is introduced around the electrode 3 at 5. As the charge enters the reaction zone 1, the carbonate is converted into cyanide. It is necessary to charge the potassium carbonate at the side of the furnace on which the nitrogen gas is introduced. The electrodes 3, which supply the heat necessary to carry on the reaction are water-cooled, and the introducing of the nitrogen gas around the electrode also aids in cooling. The temperature of the furnace is raised sufficiently high to gasify the cyanide formed, and any potassium carbonate which is gasified has to pass through the glowing carbon before reaching the gas outlet 18, since the carbonate is charged in the opposite side of the furnace. The gases are led to a condenser 7; where the cyanide is condensed. The gases not condensed are led back to the furnace through line 19. Any slag formed from the ash of the charcoal or other ingredients is tapped at 25.

Barium compounds may also be made, if necessary modifications are made in view of the higher melting points of the raw barium materials.

In the synthesis of ammonia by this method which has been tried before with little success, the cyanide is an intermediate product. The cyanide, formed as described above, except with the use of KOH instead of K_2CO_3 , is led in the gaseous state through chamber 18, without condensing, and led back to the furnace shaft at a higher level through conduit 19, where it meets steam introduced through a jet. The cyanide is decomposed, and the KOH regenerated with the formation of ammonia. The KOH passes through the process again while the ammonia is led off through the tap.

Auxiliary electrodes may be used at a point near the introduction of the cyanide gas and the steam to facilitate the reaction. (1,186,921, June 13, 1916.)

Production of Calcium Cyanamid.—In the production of calcium cyanamid from calcium carbide and nitrogen it has been found desirable to keep the temperature as low as possible due to the reversibility of the cyanide reaction. The reaction temperature has been reduced by the aid of catalytic substances such as calcium chloride or calcium fluoride. Another reason for the maintaining of as low a reaction temperature as possible was that undesirable sintering and dissociation took place at a temperature a few hundred degrees above the normal reaction temperature, and this temperature might easily be reached on account of the reaction being exothermic. According to a patent of JOHAN HJALMAR LIDHOLM, of London, England, a temperature considerably in excess of the sintering temperature may be used without a corresponding increase in dissociation if the carbide is passed rapidly through an atmosphere of nitrogen and cooled quickly.

A temperature of 2000 deg. C., is used in an electric furnace constructed as shown in Fig. 2. The furnace consists of a tube made of carbon having at its upper end a feeding hopper 4, with screen 5 to sift the par-

FIG. 2—CALCIUM CYANAMID FURNACE

ticles down into the furnace. The furnace is heated by resistance from contact blocks 2 and 3. At the bottom of the furnace is a water-cooled metal section 6 through which the newly formed cyanamid passes to a screw

conveyor 7, by which it is conveyed from the furnace. The nitrogen is introduced through pipe 9 into a space between the outside shell 8, and the furnace tube. This space is filled with coke and serves to preheat the nitrogen and abstract any oxygen contained therein. It is claimed that yields approaching very closely to theoretical may be obtained by this method. (1,184,109, May 23, 1916.)

Flotation Machine

An apparatus for applying the oil-flotation process, known in the industry as the K & K machine, is patented by FREDERICK B. KOLLBERG and MAX KRAUT, of Bisbee, Ariz. It is shown in vertical transverse section in Fig. 3. It consists of a revolvable cylinder or drum

FIG. 3—FLOTATION MACHINE

14, covered with cleats forming longitudinal riffles, moving anti-clock-wise in a close housing in a spraying chamber 1. Ore-pulp to be treated is admitted through opening 5. The spraying chamber has connection with the frothing chamber 3 by way of openings 7 and 8. Air supply pipes 23 communicate with the upper end of the spraying chamber, and oil supply pipes 26 communicate with the interior of the same. In operation pulp exists in the spraying chamber to such a depth that the drum is slightly immersed. In rotation of the drum a certain portion of pulp adheres and is carried around and thrown by centrifugal force through the openings 7. Ample opportunity is afforded for complete aeration and oiling of the pulp by the rapid revolution of the drum. (1,174,737, March 7, 1916.)

Welding

Welding Scrap Nickel Anodes.—In nickel plating work, after the anodes have been consumed to the extent of 75 to 85 per cent they become ineffective and new anodes must be used. The old anodes are scrapped and returned to the manufacturers to be remelted and recast. In a novel process patented by JAMES J. WALSH of Indianapolis, Ind., and assigned to the Prest-O-Lite Company, Inc., of Indianapolis, Ind., it is proposed to weld these scrap anodes together and use them again as new anodes. The welding is done by the oxy-acetylene flame, by heating two scrap anodes to the fusing point and then depositing hotter molten nickel on the joint, thus building up a homogeneous joint. A number of anodes are thus joined until the size is sufficient for use in the plating bath. (1,185,959, June 6, 1916.)

Alloy for Arc Welding.—An alloy to be used in the arc welding of iron and steel is patented by DAVID H. WILSON, of Paterson, N. J., and SANSOM M. RODGERS of Pittsburgh, Pa. The alloy consists of iron, manganese, copper, and carbon; successful proportions being 0.60 to 1.00 per cent manganese; 0.25 to 0.40 per cent copper, 0.18 per cent or less of carbon and the balance, iron. With these proportions a desirable voltage is 35 with electrodes 0.15 in. in diameter. The excess of manganese and copper, over the amount burned out in the arc has the effect of preserving the strength of the weld to a greater extent than formerly. The manganese protects the carbon and the iron, and the copper

reduces the melting point of the alloy and thus the welding temperature. It has been found desirable to weld at the lowest temperature possible, as the welding metal is less affected by the arc, flows more evenly and makes a better weld. (1,187,411-12, June 13, 1916.)

Sodium and Alkali Metals

Electrolysis of Fused Alkali Chlorides.—An apparatus for the production of alkali metals from alkali chlorides such as sodium from sodium chloride is patented by JOHANNES PFLEGER and FRIEDRICH OTT, of Frankfort-on-Main, Germany, and assigned to the Roessler and Hasslacher Chemical Company of New York. The apparatus is similar to the Castner apparatus in which fused caustic alkali is electrolyzed with the production of sodium. The application of the Castner apparatus to the electrolysis of sodium chloride has been previously tried and was the subject of German Patent No. 236,804. In this patent it was proposed to use two partitions separated from each other, made from different materials for the separation of the products by electrolysis. This scheme was, however, too complicated.

In the present patent it is claimed that all that is necessary is to make the part of the apparatus which is subject to chlorine gas, proof against this gas, and then the sodium chloride may be successfully electrolyzed. A diagram of the apparatus as so arranged is shown in Fig. 4. A receptacle A, of iron serves as a

FIG. 4—CROSS-SECTION OF ELECTROLYTIC APPARATUS

container for the electrolyte and electrodes. The cathode 1, is of iron and the anode 2, of carbon. The electrodes are separated by a wire screen 3, which is connected with an iron receptacle 4, covered at the top. The outside of this iron receptacle is covered by a preparation 5, which is not attacked by chlorine gas. This preparation consists of asbestos thread impregnated with a thin paste-like mixture of water, glass and asbestos flour. This is wound around the vessel, and is ready for use when dry. The use of solidified salt as the chlorine resisting material is the subject of a second patent. In the operation of the cell the sodium formed collects at the cathode in 4. The chlorine escapes through pipe 7. (1,186,936, June 13, 1916.)

A Pneumatic Powdered Coal System

The use of powdered coal as a fuel has received very considerable attention in the metallurgical industries during the last few years; after, in the Portland cement industry, it had found a wide application for a long time.

tance from the furnaces, and it is necessary that the distributing system be efficient.

The essential features of the Holbeck system are shown in Fig. 1. Bituminous crushed, nut or slack coal is stored in a bin, preferably made of steel or concrete. The coal passes from the bin and an automatic

FIG. 1—DIAGRAM OF POWDERED COAL SYSTEM

For reverberatory furnaces powdered fuel is used on a large scale at Copper Cliff and Anaconda.

For metal heating furnaces an interesting system has been developed by A. A. HOLBECK of the Bonnot Company, Canton, Ohio. This system, which is supplied by the Bonnot Company, makes it possible to distribute the fuel to widely scattered furnaces. The coal-pulverizing plant is necessarily located some dis-

tance from the furnaces, and it is necessary that the distributing system be efficient. As the coal becomes pulverized it is thrown up into the vacuum separator 1 by the action of the pulverizer. This separator separates the fine particles of coal dust from the coarse, the finest being drawn into the exhauster 2, the coarse falling down into the pulverizer.

From the exhauster 2 the powdered coal is blown into the collector 3. The expansion of the air as it enters the collector permits the coal dust that is carried in suspension to fall to the bottom of the collector and into the coal storage tank 4. The air that enters the collector returns through pipe 5 to the pulverizer to be used over again.

The coal dust is taken from the storage tank 4 by the feed screw 6 and delivered into the suction side of high-pressure blower 7. It is then blown into the distributing main 8, and carried to the furnace through the distributing pipes 9.

The coal which is not used at the furnaces is returned through the return line 10 to the collector 3, where it is extracted from the air and falls into the coal storage tank 4 to be used over again.

The air after the coal is extracted is returned to the suction side of the blower through pipe 11. The products of combustion from the furnaces are collected by the hoods 12 placed in front of each furnace, and are disposed of either by means of an exhaustor or a stack.

In Fig. 2 is shown an ingot-heating forge furnace equipped with this system, showing the powdered coal connections and burners.

FIG. 2—INGOT HEATING FORGE FURNACE EQUIPPED FOR POWDERED COAL BURNING

A Comparison of Oxy-Hydrogen and Oxy-Acetylene Cutting

BY WALTER P. SCHUCK

The recent installation throughout the country of plants producing oxygen by the electrolytic process has resulted in many cases in the production of a comparatively large amount of pure hydrogen as a by-product. The uses to which this hydrogen can be put are consequently of commercial importance. It has been well known that hydrogen in connection with oxygen is essential for cutting thick plates of steel. For cutting steel plates up to about 5 in. thick acetylene can be used for the pre-heating flame, but heavier sections require the use of hydrogen.

Even with this known advantage of hydrogen there are fewer makes of cutting torches adapted to the use of hydrogen with oxygen than those adapted to the use of acetylene with oxygen. This is probably due to the fact that hydrogen is less extensively used with oxygen for welding than acetylene, and most cutting torches are developed by makers of oxy-acetylene welding torches. Recently a combination cutting torch, known as the "Modern," that can be used with either oxy-hydrogen or oxy-acetylene by changing the tips, was developed, and while it does good work with acetylene the trials showed the use of hydrogen to be so much more economical that the writer was requested to observe a series of tests and measure the gas used.

The procedure in these tests was to first determine the minimum pressure of oxygen that would satisfactorily cut the thickness of steel on trial, and then measure the speed of cutting and the amount of each gas used. The pre-heating gas, whether hydrogen or acetylene, was delivered to the torch at the pressure necessary to maintain the proper flame with the valve at the torch wide open. The oxygen used in connection with hydrogen or acetylene for the pre-heating flame had to be regulated by means of the valve on the oxygen line at the torch, because the oxygen pressure in the hose to the torch had to be heavy enough to do the cutting required. After the proper oxygen pressure had been determined a convenient length of cut was made and timed by taking the time from the instant the cutting jet of oxygen was started until the cut in the steel was finished.

The oxygen used for each thickness of steel was measured by a counterpoised gas meter, by shutting off the hydrogen or acetylene at the torch and leaving the

In terms of the amount of gas used per lineal foot of cut and the cost of cutting, these data present some very interesting facts as shown by Table II.

TABLE II
Gases Used per Lineal Foot of Cut, and Cost of Gases per Lineal Foot.

Thickness of Steel, Inch	Oxy-hydro.	Oxy-acety.	Oxy-acety. (Acet. 1c)	Oxy-Acety. Oxygen Only
$\frac{1}{4}$	\$0.016	\$0.043	\$0.034	\$0.027
$\frac{1}{2}$	0.037	0.096	0.078	0.064
1	0.071	0.165	0.142	0.124
$1\frac{1}{2}$	0.093	0.215	0.187	0.164
2	0.114	0.291	0.259	0.230

The cost of oxygen was taken at 2c. per cubic foot, hydrogen at $1\frac{1}{2}$ c. per cubic foot, and acetylene at $2\frac{1}{4}$ c. per cubic foot, and also at 1c. per cubic foot. The amount of oxygen required when using acetylene as the source of heat for pre-heating is so much greater than when using hydrogen that it would be cheaper to use the oxy-hydrogen process at the prices named, than to use oxy-acetylene even if the acetylene were obtainable free of cost. This seems such a strong showing in favor of the oxy-hydrogen cutting that an explanation should be had.

The writer believes that in view of the well-known deleterious effect of even small amounts of the non-combustible gases when cutting steel with oxygen (see Tucker, *Journal of the Society of Chemical Industry*, Vol. XXX, page 779, July 15, 1911) the low efficiency of oxy-acetylene cutting can well be explained by the presence of the carbon dioxide resulting from the combustion of acetylene. A part of the gases resulting from the combustion of either hydrogen or acetylene are drawn into the cut by the suction of the oxygen jet. In the case of hydrogen this means that water vapor and nothing else will dilute the oxygen used for cutting, while with acetylene both carbon dioxide and water vapor are introduced. This is clearly shown by the chemical equation of the union of these gases with oxygen.

These equations, however, show only the molecular relation of the combustion of these gases, and for a true understanding of the amount of carbon dioxide involved the volumes entering into the reaction as shown in the following must be considered.

In short, this means that the complete combustion of one volume of hydrogen produces one volume of water vapor, while acetylene produces its own volume of water vapor plus twice its volume of carbon dioxide. This additional carbon dioxide dilutes the cutting jet of oxygen to such an extent that a great deal more must be used than is necessary when burning hydrogen.

The gases used in these tests were: electrolytic oxygen 99.5 per cent pure, electrolytic hydrogen 99.8 per cent pure, and acetylene from a commercial tank of com-

TABLE I

Thick-ness of Metal, Inch	CUTTING SPEED Ft. per Hr.		PRESSURES AT WHICH GASES ARE USED				GAS CONSUMPTION, CU. FT. PER HR.			
	Oxy-hydro.	Oxy-acety.	Oxy.	Hydro.	Oxy.	Acety.	Oxy.	Hydro.	Oxy.	Acety.
$\frac{1}{4}$	90	100	5	2	12	10	47	35	110	71
$\frac{1}{2}$	45	50	5	2	15	10	56	45	160	71
1	16	39	12	5	35	10	90	71	242	71
$1\frac{1}{2}$	35	32	15	5	40	10	101	71	263	71
2	30	28	20	5	55	10	123	71	327	71

oxygen flow from the torch just as it had while making the cut. To guard against any back pressure in the gas meter, due to friction, a water-filled U-gage was connected to the intake pipe of the gas meter and the water in it kept level during the passage of the gas and when it was measured. The hydrogen and acetylene were measured in the same way after the flame had been relighted, adjusted and then the oxygen shut off and the flame extinguished by putting the torch under water. Table I gives the data derived from these tests.

CUTTING TESTS

pressed gas held in solution by acetone. These tests were all made using the torch moved by hand along a guide and represent fair average practice with the equipment mentioned. With gases of poorer quality, such as oxygen made from air, the speeds given can not be maintained and greater pressures must be used.

A trial of cutting 1-in. steel plate was made using atmospheric oxygen with hydrogen and also with acetylene, and the results are clearly shown in the accompanying photograph. Each of cuts numbered 1, 2, 3 and 4 represents the longest cut possible to make in this material in two minutes, using the same size cutting tip and the least pressure of oxygen that will make a thorough cut. Cut No. 1 was made with electrolytic oxygen 99.5 per cent pure and electrolytic hydrogen. Cut No. 2 was made with electrolytic oxygen 99.5 per cent pure and acetylene. Cut No. 3 was made with atmospheric oxygen 97.4 per cent pure and electrolytic hydrogen. Cut No. 4 was made with atmospheric oxygen 97.4 per cent pure and acetylene. All previous cuts were covered and not visible to the operator when making a cut.

Portland, Oregon.

Personal

Mr. David F. Baker, formerly connected with the blast furnace department of the Broken Hill Proprietary Company at New Castle, New South Wales, is in this country and will take up permanent work here.

Dr. Wallace P. Cohoe has moved his office and laboratory from the Chemists' Building, 50 East Forty-first Street, New York, and has taken an office in the Trinity Building, 111 Broadway. His laboratory has been moved to Bertrand Avenue, Perth Amboy, N. J., where he now has facilities for carrying out investigations under manufacturing conditions.

Mr. F. G. Cottrell was in Denver recently in conference with officials of the Bureau of Mines. He expected to visit Anaconda and other western plants before returning to Washington.

Mr. Noel Cunningham, formerly of the Dorr Company, has opened an office as consulting metallurgical engineer at 200 Fifth Avenue, New York.

Prof. H. O. Hofman, of the Massachusetts Institute of Technology, has been making a trip through the West visiting lead smelters at Chicago, Omaha, East Helena, Northport, Trail, Selby and Tooele.

Mr. W. R. Hulbert, sales manager of the Goldschmidt Thermit Company of New York, delivered an illustrated lecture, supplemented with practical demonstrations, on the theory and practicability of making thermit welds, to the members of the Clinchfield Railway Club, at Erwin, Tenn., on Tuesday evening, July 25.

Mr. Robert M. Keeney has been in Denver on professional business.

Mr. Karl L. Kithil will be in charge of the new station of the Bureau of Mines recently established at Tucson, Ariz. For several years past he has been on the bureau's staff at Denver.

Mr. Van H. Manning, director of the Bureau of Mines, is on a trip of inspection to the western stations of the bureau. He expects to select the location for a northwestern station before his return.

Mr. Ernest B. Nelson, formerly connected with the Chile Exploration Company, Chuquicamata, Chile, has accepted a position with the Andes Exploration Company, Chanaral, Chile.

Mr. Charles Pascoe, formerly metallurgist for the Canadian Steel Foundries, Ltd., and recently connected

with the Thos. Davidson Manufacturing Company, Ltd., of Montreal, as consulting metallurgist, has joined the Snyder Electric Furnace Company of Chicago, Ill., as metallurgist in that company's electric furnace research plant at Clearing, Ill. Mr. Pascoe's work in connection with the Thos. Davidson Manufacturing Company had to do with the production of shell billets from a Snyder electric acid steel furnace. Mr. Douglas Walker, former salesman for the Snyder Electric Furnace Company, and in charge of the Chicago district, has been appointed sales manager.

Mr. W. G. Savage, associated for many years with the Chicago office of the United States Cast Iron Pipe & Foundry Company, has been appointed assistant sales manager in charge of Western territory.

Mr. H. W. Seldon, manager of the metallurgical department of the Scientific Materials Co., Pittsburgh, Pa., has resigned to become assistant to the superintendent of the Franklin Open-Hearth Department of the Cambria Steel Co., at Johnstown, Pa.

Mr. Louis E. Strathman, manager and chief engineer of the pumping department of the Allis-Chalmers Manufacturing Co. of Milwaukee, Wis., was recently elected president of the Engineers Society of Milwaukee.

Mr. Melbert W. Taber, formerly manager of maintenance and construction of the Packard Motor Car Company, has been appointed manager of the Detroit office of the Asbestos Protected Metal Company of Pittsburgh, Pa. The Detroit office is located in the Penobscot Building.

Industrial Notes

The J. P. Devine Company, Buffalo, N. Y., has recently issued Bulletin 101 describing vacuum chamber dryer units that are adapted for the drying of materials that can be handled on trays or pans; Bulletin 102, describing the Devine vacuum drum dryers, adapted for all liquids and solutions containing solids, drying same to a powder; and Bulletin 103, describing Devine vacuum rotary dryers that are used in connection with drying materials that can be mixed or tumbled in the drying.

The School of Applied Industries of the Carnegie Institute of Technology, Pittsburgh, Pa., has completed its first decade in industrial education and the results have been highly gratifying. Almost 10,000 students have been enrolled at some time or other during these years, 476 of whom have been awarded diploma or certificates of graduation. Four industrial courses covering three years each are offered, viz.: machine construction, building construction, general equipment and installation, and printing. A one-year intensive trade course is also offered. The school has been under the direct charge of Dean Clifford B. Connelley.

Russian Trade.—R. Martens & Co., Inc., New York, exporters, are expanding their export operations in Russia. The original purpose of limiting their operations to the mechanical lines of industry will be strictly adhered to. But to conserve the tremendous opportunity for non-mechanical lines, they have created a subsidiary company under the name of "Russia Trade Corporation of America." The new concern will have a complete business organization and its general offices will be in the Maritime Building, 8 and 10 Bridge Street, New York, and all business transactions will be entirely separate and distinct from the parent company.

Messrs. Eimer & Amend, New York City, have filed plans for the new ten-story addition which will be

built to the present store at Third Avenue and Eighteenth Street. The cost will be \$100,000.

The Improved Equipment Company, 60 Wall Street, New York, has added a new department, to be known as the Boiler Department. This department will offer its services for the design of steam boiler furnaces, hand fired; automatic stokers, forced-draft equipment for all types of furnaces and stokers; oil, tar and gas burners and complete plants for these fuels; pulverized and crushed coal furnaces and apparatus.

The Sarco Co., Inc., New York, have appointed Newton-Johnson, Sales Engineers, as sales representatives in Wisconsin and the northern peninsula of Michigan.

The John A. Crowley Co., Detroit, Mich., announce the sale of 2 Gronwall-Dixon furnaces which will be installed shortly. One of these furnaces will be used for sheet bars and the second for high-grade tool steel.

The Titanium Alloy Mfg. Co., Niagara Falls, N. Y., has recently added to its bronze department sales force Mr. Gilbert T. Mason, formerly secretary and treasurer of The Atkinson Co., Rochester, N. Y.

The Colorado Iron Works Company has issued Pamphlet 24-B describing the Akins classifier, Pamphlet 9-B describing the Impact screen, and Pamphlet 30 describing crushers and rolls.

The Nash Engineering Co., South Norwalk, Conn., has issued Bulletin No. 5, describing the Nash hydro turbine, air compressors and vacuum pumps, single-stage type.

The American Blower Company, Detroit, Mich., has issued Bulletin No. 17, series 3, describing "A, B, C" heaters for use in heating, ventilating, and air conditioning work; and Bulletin No. 17 series 4, describing "A, B, C" unit heaters for special work in various industries.

Instruction Book on Oxy-Acetylene Welding and Cutting.—A nicely arranged little book has been gotten up by the Prest-O-Lite Co., Inc., of Indianapolis, Ind., on the practice of oxy-acetylene welding and cutting. The authors are H. Sidney Smith and A. F. Brennan. The purpose of the book as stated in its preface is to present, in the simplest language, a brief description of the practical application of oxy-acetylene welding and cutting in the metal trades. It has been written especially for the man with little or no knowledge of the process.

New Refinery Construction in Baltimore.—The Baltimore Copper Smelting & Rolling Co., Baltimore, Md., began work Aug. 3, on the construction of an addition to its plant to include 700 tanks. The contract for the lead burning was awarded to H. G. Klink of Whiting, Ind.

Synthetic Ammonia.—The Badische Anilin und Soda Fabrik, Ludwigshafen, Germany, has increased production greatly at its new plant producing ammonium sulphate by the Haber process. According to the *Chemical Trade Journal and Chemical Engineer* (London), the large demand for fertilizers in Germany, since the outbreak of the war, due to imports being stopped, is responsible for recent large extensions at this plant, over 2000 men now being employed. Still larger works are now being built near Carbetha, on the Saale, which will employ 6000 persons.

New Oil Refinery.—The Sinclair Oil & Refining Corporation plans the construction of an 8-in. pipe line from the Oklahoma fields to Chicago and the erection of two refineries, one at Chicago and the other at some point on the Mississippi River. The pipe line will cost \$8,000,000, the refineries costing about \$2,000,000.

Warren Webster & Company, Camden, N. J., has issued a beautifully illustrated catalog describing the Webster vacuum system of steam heating. An outline is given of the development of the apparatus, followed by a description of its design and installation. Other special Webster features are also described, such as feed-water heaters, meters, steam separators, traps and air-conditioning apparatus. A series of photographs of buildings in which Webster apparatus is installed is included.

Locomotive Cranes.—The Brown Hoisting Machinery Co., Cleveland, Ohio, has issued an illustrated booklet describing Brownhoist locomotive cranes. These cranes have found application in railway work, contracting, steel, coal, lumber, mining and manufacturing industries. The catalog describes the different operations, showing how and where some of them are used.

Large Junk Pile in 1915.—The recovery of secondary metals in 1915, as given in the report of the Geological Survey by J. P. Dunlap, shows a great increase over the 1914 recovery both in amount recovered and in the value of recovered products. The secondary metals include copper, lead, zinc, antimony, tin and aluminum. The value of these metals recovered was \$114,304,930 in 1915 as compared with \$57,039,706 in 1914. The amount recovered was close to 400,000 short tons as compared with about 286,000 short tons in 1914. The high price of metals in 1915 stimulated efforts to save scrap and caused the refiners of scrap to work to the limit of their capacity. Dealers in and smelters and refiners of waste metals experienced the greatest period of prosperity ever known. The statistics of secondary metal recovery are valuable as an adjunct to the primary production as they show the total amount of the metals available for consumption.

SECONDARY METALS RECOVERED IN THE UNITED STATES IN 1914 AND 1915

Metal	1914		1915	
	Quantity (Short Tons)	Value	Quantity (Short Tons)	Value
Secondary copper, including that in alloys other than brass.....	58,556	\$15,435,362	99,937	\$33,498,882
Remelted brass.....	99,088	21,034,300	137,500	40,788,000
Secondary lead.....	29,337		36,400	
Recovered lead in alloys.....	31,725	4,762,836	42,500	7,416,600

		57,039,706		114,304,930

Book Review

The American Fertilizer Handbook for 1916. Ninth annual edition. 400 pages; price \$1.00. Philadelphia, Ware Bros. Company.

This is the ninth annual edition of this valuable handbook relating to the fertilizer industry. The directories of fertilizer manufacturers, cottonseed oil mills, allied trades, packers and renderers have been carefully revised up to date. Statistics for 1914 and 1915 of potash and nitrogen products, as furnished by the Geological Survey, are included in the book. Special articles are included on the Cyanamid Industry-World Status, by E. J. Franke; Preventable Losses in Fertilizer Plants, by S. J. Martenet; Possible Sources of Potash in America, by Frank K. Cameron, and The Sulphuric Acid Industry, by Andrew M. Fairlie.

Two Coming Technical Society Events

The last two weeks of September will bring two technical society events of nation-wide importance. During the week of September 18 the American Institute of Mining Engineers will meet in Arizona, now easily the leading copper-producing State. This will be the first Arizona meeting in the Institute's history of forty-five years. Sessions will be held in the principal mining centers of the State, the members traveling between the various points by special trains and automobiles. An excellent technical program has been arranged, including an important discussion on concentration and flotation. The principal sessions will be held at Santa Rita and Hurley, N. M., and at Douglas, Bisbee, Globe and Phoenix, Ariz. The inspections will include the Roosevelt Dam, the mines and works of the Chino Copper Co., the Copper Queen Consolidated Mining Co., Calumet & Arizona Copper Co., Shattuck Copper Co., Inspiration Consolidated Copper Co., Miami Copper Co., Old Dominion Copper Mining & Smelting Co., together with the new works of the International Smelting Co. There can be no doubt that the Arizona meeting will be as enjoyable and successful as the unforgettable Montana, Utah and California meetings of the past three years.

The week of September 25 will be Chemical Week in New York City. The Second National Exposition of Chemical Industries will be held at the Grand Central Palace, and it is now assured that it will be even bigger and more representative than the immensely successful First Exposition of last year. In conjunction with the exposition the two largest national chemical societies of this country—the American Chemical Society and the American Electrochemical Society—will hold meetings in New York City, and unusual efforts are being made to render these events as enjoyable and profitable as possible.

The only pity is that the Arizona meeting of the Mining Engineers and the chemical exposition and conventions come so near together as to make it practically impossible for any one to attend both events. Yet mining engineers and chemists would do well to try and get a little bit better acquainted.

Steel Capacity After the War

The American iron and steel industry never shows a perfect alignment as to capacity in the different departments. All departments strive for maximum output when the market will absorb the product and every period of activity witnesses wholesale breaking of records whereby balances between departments are disturbed. Then there are fluctuations in the alignment of demand, the consumption of some finished steel

products increasing more rapidly than that of others. In 1903 the production of structural shapes was 27 per cent less than the production of wire rods; in 1913 the production was 22 per cent greater. Until 1904 the production of rails exceeded that of plates and sheets; in 1913 plates and sheets exceeded rails by 64 per cent.

The war has furnished the greatest disturbance of all, and the alignment of capacities in the different departments at the close of the war will doubtless be found quite unsuited to the conditions of a peace demand. There has been a remarkable increase in the production of ingots, as compared with the production of pig iron on the one hand and of finished steel on the other. A part of the increase in ingot production is attributable to the unusually large supplies of heavy melting steel available, due to the heavy cropping involved in the manufacture of shell steel, and this excess will automatically disappear. Apart from this increase, however, there has been an increase in the steel-making capacity relative to finishing capacity, and this will not disappear. The excess is represented at present in the exportation of large tonnages of forging billets and other unfinished steel, together with large tonnages of rounds rolled on rail mills. The rail mills are very busy, although the domestic demand for rails has been relatively light.

The most striking lack of harmony disclosed by the actual market prices prevailing is the shortage of steel-making capacity relative to pig-iron producing and steel-finishing capacity, whereby there is an unprecedentedly large gap between pig-iron prices and unfinished steel prices. Basic pig iron has been selling at an average price of \$19 to \$20, delivered at steel works, while billets, slabs and sheet bars are quoted nominal at \$45 to \$50, being almost unobtainable at any figure. Light gage sheets and wire nails are selling at considerably less than the bare cost of conversion above the current market prices for their raw materials. The market price of unfinished steel is not made by demand for sheet bars, or perhaps, even for billets, in the domestic market, but is caused by high bids for slabs from domestic plate mills, and by heavy export demand for nearly all descriptions of unfinished steel. After the war the alignment will necessarily be quite different. Pig iron and unfinished steel will not be so widely separated. Plates will not sell at \$8 a ton more than structural shapes.

Tied Hands

We are just as patriotic as the next fellow; we hold the fair name and fame of our beloved land as a sacred thing and we do not believe in carping criticism. But sometimes we get a little confused. We stand by the Constitution, but we do not always know just which way to look while we are standing there. For instance, here is a letter from the Director of the United States Geological Survey to one of the managers of the Chemical Exposition, which we print with permission: "I regret with you that there is practically no possibility of Congress passing a bill appropriating funds to allow the Government Bureaus participating in the Second Na-

tional Exposition of Chemical Industries. In view of Congress' apparent desire to prevent the various bureaus taking part in this project as well as its former order against allowing employees to be detailed to scientific meetings, etc., at the expense of the Government, I am constrained to inform you that it will not be possible for the Survey to send an exhibit to New York for the exposition and it will therefore be unnecessary to hold space for our use. I trust that several of the chemists and geologists will be able to visit the exposition on leave at their own expense, and I hope that you will meet with the same success that attended the first exhibit of this sort."

It is all right for Congress to hold a tight rein upon the Government, but does it take a special bill to send up a little exhibit? The work of the Government for the people needs to be brought to their attention so that they may know what it is doing—at least, so it would appear—and yet Congress, so lavish with post-office buildings for small towns and special pensions that have been refused by the pension authorities and the dredging of small creeks for the "extension of commerce," seems to think otherwise.

That will be quite an exhibit in the last week in September, and if present signs do not fail, it will be very largely attended. The Geological Survey works for all the people. It costs far less than pensions and it is more useful and more interesting. It knows a great deal about the mineral deposits of the country and industry would like very much to be posted. This would extend commerce far more than many of the duck ponds for which Congress has made such generous appropriations. Maybe Director Smith draws too fine a line in regard to the authority vested in him, and yet if he can't exhibit, we don't see how he can. It is confusing; very confusing. Especially as the Bureau of Mines is sending a very considerable exhibit.

The Byproduct Coke Oven

In our issue of July 15 (page 56) we commented on the marvelous rate at which the iron industry of this country is now adopting the by-product coking process. But as a remark at the end of that note concerning the by-products recovered has been misunderstood, it may not be amiss to restate the situation exactly. The facts are that there are practically no by-product coke plants in the United States, which do not recover ammonia, tar and light oil (crude benzols). In the vast majority of the plants also surplus gas is recovered and utilized either at the plant itself or by distribution to outside consumers. There are possibly two or three very small by-product coke plants at which tar and ammonia are not recovered for disposal to the outside markets, but these would certainly represent considerably less than 1 per cent of the total by-product coking capacity. There is not over 5 per cent of the by-product coke oven capacity of the country that is not now equipped with benzol recovery plants, and the by-product coking plants now under construction have either contracted for benzol recovery equipment or indicated a strong probability that such provision will be made.

This development is industrially important and interesting in more than one direction. We may consider the utilization of the by-products recovered and rejoice of the foundation of new industries in this country. This is perhaps the most natural way to look at the by-product coke oven development. But we may also consider the effect which this development has had on the iron industry. One of the most interesting technical effects is brought out very clearly in the article by Mr. J. E. Johnson, Jr., on commercial considerations concerning the blast furnace, published in this issue. A few years ago maximum degree of fuel economy was not only technically desirable, but was commercially necessary for survival, but this is no longer the case. There are conditions in which the commercial results are better with very moderate fuel economy than with the highest. The two developments which have brought about this change are the introduction of the by-product coke oven and the economic development of power generation with blast furnace gas, especially the gas engine. Mr. Johnson's very lucid demonstration of this peculiar situation should be read with decided interest.

The Commissioner of Chemistry

There is a man in Jamaica, Long Island, who has a boy named Donald, twelve years old. He left home for a visit to Mount Beacon, N. Y., and he returned a week later. "When Donald went away," said his father to a New York World reporter, "he was four feet ten inches in height and weighed seventy-two pounds. When he got back to-day his mother was so amazed at his appearance that we measured him again and found that he was five feet two and three-quarters inches tall and weighed eighty-two pounds."

He had grown four and three-quarters inches in eight days.

Donald is like some chemical industries in this country in that both have made a record growth, but there the resemblance ends. Donald has a father and mother to look after him, to discourage cigarettes and wet feet and bad companions. It is not so with many of our blooming young chemical industries. They have no father and mother to look after them. What will they do on the day when they get cold feet?

Some time or other the big war will be over and ships will be sailing on the seas. The Japanese have entered into the chemical habit, and a lot of munition works in the Rhine country will shift back into making other chemical products. They can do it because the equipment is there. The reporter who thought that all the shell makers and TNT institutions and "Pickwick Acid" layouts in the United States could shift over into making alizarine and indigo and fast cotton colors and intermediates and all the wanted things, by a twist o' the wrist, was wrong; but over in Germany the equipment and the art to make the things they used to produce will be available. Chemical manufacture is growing in Norway and Sweden by leaps and bounds, and England has developed a chemical consciousness. The Scotch have taken to chemistry, and that means trouble—outside of Scot-

land. In all of the countries mentioned there is great encouragement for manufacturers to get together and co-ordinate their work. Every country is resolved to be self-contained or burst a lung in the attempt, and every country is also firmly resolved to cultivate and prosecute an active export trade. Now, nobody outside of Congress believes that in American chemical industry there is good, co-ordinated system. And the time is coming when these efforts at export trade will be made by sister nations on every hand. Then we can talk protection until we are blue in the face and insist upon it that the man who buys foreign goods is without patriotism and we can call him a traitor and all the hard names we can think of—but nothing will help except system and order and co-ordination.

So chemical industry needs a leader who is long on knowledge and experience in the markets as well as in industry; who can say disagreeable things and yet be cheerful about it, and who is not committed to any particular organization. He should be a successful man who has made his pile and who has a liking for bringing about results. The place for him would be in some department of the government at Washington, where information would come to him at first hand and where he could do some co-ordinating without breaking the law.

This sort of thing can only be done from the Heights of Government. We have the grave difficulty that only Government may do those things that business men may do in most other countries. Under the Sherman law, a tricky lawyer can construe nearly every manufacturer, no matter how conscientious and innocent of all evil he may be, into a criminal by a possible "theory of the case"; and American manufacturers have lost initiative under it. Some manufacturers' associations have dwindled down into weak imitations of a comedy hen-party in which the talk, restricted to the difficulties with household servants, is changed over into talk restricted to the guile and the wiles of labor unions. The iron and steel industry is in good shape because manufacturers learned the value of co-operation before the Sherman law broke out and they have the habit of keeping themselves posted. The chemical industry is not in this condition and manufacturers are not posted. And they dare not post themselves save under a standing threat from the Attorney General.

The Agricultural Department keeps farmers informed about the wheat crop, the cotton crop, foreign production and the markets. Why not do the same for chemical industry. Everybody wants chemical industry to thrive, and it cannot thrive unless it knows what is being made and landed, where it is coming from, how much of various materials are being produced and something about the markets. It needs the same kind of paternal care that it gets in other countries just as much as it needs protection.

We have no idea where the Commissioner of Chemistry would fit in, but there is room for him and need of him—unless he is to be a politician, or, in fact, any one other than a man worth far more than his salary.

Electrometallurgy of Iron and Steel and Pacific Coast Waterpowers

To the Editor of Metallurgical & Chemical Engineering

SIR:—In your issue of July 1, in a very interesting article by J. W. Beckman dealing with electrochemical possibilities on the Pacific Coast as compared with those in Sweden and Norway, reference is made to the new electrothermal iron reduction which has been developed on a very large scale in Sweden, and as I am intimately acquainted with this situation I thought some information on the point might be interesting.

Mr. Beckman states that about 50,000 tons of iron are produced annually in the Swedish electric reduction furnaces. I may say that the output is now considerably over 100,000 tons, but it may be that Mr. Beckman's figures relate to a period about two years ago. Since then very large furnaces have been built which have a capacity of 10,000 hp. each, producing roughly 25,000 to 30,000 tons of pig iron annually. Compared with the ordinary blast furnaces, this capacity is, of course, only small, but it must be remembered that a very high-grade quality of pig iron is obtained, fetching good prices.

Most of the electric-furnace installations are in the middle of Sweden, whereas the ore for several of them is transported from the far north, being hauled about 200 miles by railway, then 800 miles in ships, and then again a short rail journey at the other end. Charcoal is delivered to the iron works by the railways, and the collection area is enormously wide, so that it is not unusual for charcoal to be transported 300 miles. These facts are important when contemplating similar developments on the Pacific Coast. Mr. Beckman mentioned quite rightly that so far most of the charcoal is made direct in the forest in the old-fashioned way, but the tendency is now to concentrate in large plants, especially in connection with sawmills, where all the refuse is used for making charcoal. In such cases the plant is equipped with apparatus for distillation and preservation of by-products which, if properly done, yield so high a profit that the charcoal can be sold at a very low figure.

I venture to say that there is no place in the world where conditions are so exceptionally suitable for electric iron ore reduction as the Pacific Coast of the United States and Canada. If enterprising people went about this affair in a proper way, it should be extremely remunerative and help to develop industry generally. It would, of course, be advisable to make use of the reliable experience which has now been accumulated by Swedish engineers, and this is represented by a British firm, Electro-Metals, Ltd., of London, which controls all the American patents.

In Sweden, experiments have been carried out with many different types of furnaces, but only one type has proved to be a commercial success, and is now used at every plant throughout the country, viz., the reduction furnace belonging to Electro-Metals, Ltd.

The process has now been developed further in Sweden so that the molten pig is delivered direct to the open-hearth furnaces, heated by the gases from the reduction furnace, and, finally, the charge from the open-hearth furnace is poured into an electric refining furnace, and the final steel is of remarkably high quality. This is obviously the right method where electric current can be obtained at a reasonable price.

In this connection it will interest you to know that electric refining of steel has gained much ground during the war in this country (Great Britain). Some forty furnaces of varying capacity have been put in—most of them in the Sheffield district, but also in other parts of the country—and the success has everywhere been conspicuous. Not only is the quality of the steel such as could only be obtained previously in crucibles, but makers have found that in spite of the high price which they pay for current (approximately 1.5 cents per kilowatt-hour), there is no doubt that electric refining offers an extremely convenient and reliable method of dealing with impurities and determining a desired analysis of the steel. Any large electrothermic iron works on the Pacific Coast would be complete only with final electric refining as indicated above.

Red-Hot Summer-Day Inventions

To the Editor of Metallurgical & Chemical Engineering

Sir—The man with a chemical past went to the Chemists' Club for luncheon. At a table in the Julep Garden sat three men at meat, a man of research, his assistant and a professor of physics. "Sit down at our table," said the man of research; "we are having an invention bee and we want you to help us. I am doing my bit for preparedness and my invention relates to ordnance, of course for purposes of defence."

"What is it?" asked the man with a chemical past.

"It is a gun," said the research man, "a four-foot gun. I mean four feet in diameter. You see, the trouble with the big guns of the present is that they are fired at an angle of thirty-five degrees and the projectile meets resistance from the air throughout its entire trajectory. With my bigger gun it will be possible to shoot at a much greater angle, and, given enough explosive force, when the projectile reaches a distance of eight miles above the earth, the air friction will become negligible, so the distance may be increased in proportion to the charge. Of course, to resist a force of such violence an extraordinary density of material will be required, and I have concluded that this may be obtained at very low temperatures. To meet this I propose the use of liquid air, and for a metal I have chosen mercury."

"Details to be worked out, I suppose," suggested the professor of physics.

"Certainly," answered the man of research. "I claim for my invention sufficient tensile strength to meet the requirements. I am only worried by two features: one is how to rifle the bore and the other is the nature of the projectile."

"Why don't you use a squirrel-cage device to twist your projectile around lickety-split before you fire her off?" asked the professor of physics.

"My hearty thanks, dear colleague," answered the man of research. "Your suggestion is gratefully accepted. It is merely a problem in engineering. We may count that feature as settled. Then, you observe, having shot off a few projectiles, it may be desirable to let fly at the enemy from another point. The thing to do is to surprise him. So I plan to run the mercury by pipe line to the next best place, set up the big gun again by means of liquid air, adjust the squirrel-cage device to give the proper twist, and annihilate the re-

serves. Everything is ready to work out except the projectile; I don't know what to fill it with."

"May I come in on this?" asked the man with a chemical past.

"Why not?" replied the research man. "This is welfare work, and every suggestion is acceptable."

"Well, I've been seeking immortality for over fifty years and haven't found it yet. Here is my chance. Fill 'em with mercaptan."

"Good!" exclaimed the research man. "I accept your proposal and shall fill the projectiles as you say. Now, I think we have the whole problem of preparedness settled, with my gun, your squirrel-cage twister and your mercaptan projectile."

"I feel that there is something more important than preparedness," said the professor of physics. "I want to meet public opinion. Preparedness is only a feature of public opinion. What is universally in the public mind is the desire for a Place in the Sun. That is something that everybody and every nation wants. My invention will endeavor to meet this desire. It recognizes the great water power of the United States, only a small fraction of which is used. I propose to harness all the waterfalls, develop every one of them, and have available to be connected with each one to the full capacity of its power, a great gyroscope, or series of them. These shall all be connected with a central control station. You may go ahead with your preparedness and have as many soldiers and guns as you please, but some nation is always sure to have more of them than we have. Remember that we always have Congress at Washington, and while Congress may be active and enduring in speech, it has never yet been intelligent. At least it has not in this generation. So I plan to have these gyroscopes connected up with the State Department in Washington. Then let us suppose that we have a point at issue with some European capital. An ultimatum is given to us to do as the authorities at the foreign capital require within twenty-four or forty-eight hours, or suffer the consequences. They proceed to mobilize, and still we are indisposed to do as we are told. It is possible for nations to feel that way. Very well, as the time set in the ultimatum draws to a close and we have not obeyed, the wise man who will then be in the State Department turns a little lever, the gyroscopes all begin to turn, the mathematically computed push is given in just the proper direction, the gyroscopes push the other way, harder and harder, exactly as planned, and straightway the earth proceeds to revolve on a new axis, and London or Berlin or any other capital that gets too gay—becomes the North Pole! As soon as the ultimatum is withdrawn, another little turn of the lever brings every country back to its accustomed climate again. In time, of course, the whole world would join in the gyroscopic control of the axis of the earth, and the North Pole dip would be used for the punishment of recalcitrant nations that want to go to war when they shouldn't. It would be a great convenience, also. For instance, after the harvests are over the people of Ontario and the Middle Western States want ice for their season's store. So they send in a petition, the Great Lakes are put at the North Pole over night, and there's ice enough for everybody."

The assistant of the research man, being young in years, declared that he had no interest in public welfare, and was resolved thenceforth to live a life of sin and iniquity.

"Tut, tut!" said his principal, "what unholy thoughts are possessing you?"

"I was raised orthodox," said he, "and I stick to it, with all the fire and brimstone that's in the catechism. And I have concluded to multiply my sins and to land in

limbo. With the great heat available I expect to develop a considerable power plant. This will enable me to operate a refrigerating apparatus large enough to provide an equable temperature for my own apartment. The power plant will also serve to drive an electric generator, and this will enable me to bring down the sulphur fumes by the Cottrell method of electric precipitation. With the air thus cleared and the temperature regulated, I look forward to an enviable measure of comfort in hell."

"Just let me know," said the man of research, "when this life of sin and iniquity is to begin for the sake of order in the laboratory, and, by George, we'd better be getting there as fast as we can. We have those determinations to start, you know." The others also had work in hand and so, *exceunt omnes*, into the work-day world, where tasks are set and invention bees are discouraged.

Edinburgh Meeting of Society of Chemical Industry

The thirty-fifth annual general meeting of the Society of Chemical Industry was held in Edinburgh, Scotland, at the University of Edinburgh, July 19 to 21, 1916, and was devoted to a discussion of the progress of British chemical industries since the war. The Lord Provost of Edinburgh, Sir Robert Inches, welcomed the society to Edinburgh, and recalled the first meeting which the society held in Edinburgh in 1894. The president of the society, Dr. Charles Carpenter, then replied and took the chair. The report of the council was read, giving a review of the meetings of various committees and of the work done during the previous year.

Doctor Carpenter, in his presidential address, expressed his appreciation of the Edinburgh section, the youngest section of the society. He said the "Athens of the North" claimed homage essentially as an ancient seat of learning, a more congenial soil for the study of *belles-lettres* than for researches in dyestuffs. If art and science mutually need inspiration from each other, the meeting in Edinburgh cannot but be fruitful in

good results. The president made a strong plea for a closer relation between science and industry. He urged upon the University of Edinburgh the necessity of placing science in the forefront of its teaching, and thus setting an example to other similar large universities. Engineering and chemistry should go hand in hand to successfully develop chemical industries. The worker also should be given consideration, and profit-sharing plans make for a higher efficiency. Education of the law-makers was also urged, and the establishment of chairs of organic and inorganic chemistry at all universities, new and old. He spoke of the value of chemical meetings, and suggested the building of a permanent meeting house, to contain library, laboratory, etc.

The medal of the society was presented by the president to Mr. C. F. Cross for his services to chemical industry, especially cellulose and paper. During the meeting there was an exhibition of dyes, glass, porcelain, etc., indicating progress made in manufacturing since the war. It was decided to accept the invitation to hold the next meeting at Birmingham.

The following papers were presented:

Fuel Economy: A National Policy Required, by Henry E. Armstrong.

Recent Improvements in By-Product Coke Over Practice, by G. P. Lishman.

Waste in Coal Production, by Henry Louis.

The Shale Oil Industry, by D. R. Steuart.

The Influence of the European War on the Tar Distillation Industry, by W. H. Coleman.

The Extraction of Tar Fog from Hot Gas, by G. T. Purves.

The British Coal Tar Color Industry and Its Difficulties in War Time, by C. M. Whittaker.

The Production of Alkaloids, as Affected by the War, by D. B. Dott.

The Manufacture of Synthetic Medicinal Chemicals as Affected by the War, by Francis H. Carr.

The Manufacture of Fine Chemicals in Relation to British Chemical Industry, by C. A. Hill and T. D. Morson.

The Paper Mill Chemist in War Time, by J. F. Briggs.

The Overhauling of Our Patent Law, by J. W. Gordon.

The Influence of Patent Law Upon Industry, by Walter F. Reid.

The Disadvantage of the Present Patent Law, by W. P. Thompson.

The Progress of the British Rare Earth Industry During the War, by Sidney J. Johnstone.

The Iron and Steel Market

The steel market has continued to make progress toward a still stronger and more active condition. The \$2 a ton advance in bars, plates and shapes made by the Carnegie Steel Company early in August has been followed by all other producers and the market is now on the higher level. For a month that is normally very dull August has done quite well in the matter of new bookings, as the contract obligations written are substantially equal to the shipments. The Steel Corporation's unfilled obligations decreased by 297,340 tons during June, but by only 46,866 tons during July, and the preponderating prediction is that a slight increase will be shown for August.

There has been no excitement in the steel market in the past fortnight, the surface appearance being one of dullness, but tonnage has been booked nevertheless. There has been an export demand greater than could be satisfied as all the deliveries desired could not be compassed by the mills, and some of the domestic consuming trades have been free buyers. The automobile trade has been particularly conspicuous in urging that

contracts for deliveries over the first half of 1917 be accepted at once, even though the price might be left open. Assurance of delivery is the prime consideration in this trade. The agricultural implement makers, by way of contrast, have been very conservative in the matter of buying and insist that if steel prices are maintained at their present high level the demand for their product will be greatly reduced.

The report of the Bridge Builders' and Structural Society shows that bookings of fabricated steel contracts in July represented only 47½ per cent of a month's capacity, the smallest percentage reported since February, 1916. Freight car orders have been extremely light. The outstanding feature of the situation is the difficulty in determining how the pressure on the steel mills can be so great when several lines of consumption are decidedly slack.

Averaging the entire period July and August and the entire steel industry there has been hotter weather than in any preceding season since there was a steel industry of any proportions. The weather moreover has had an unusually great effect in cutting down production. The steel mills are but scantily manned at best and as the men are prosperous there has been more disposition to quit work when the temperature was disagreeable. The production of steel in the two months has probably been more than 10 per cent less than the production in the two months preceding.

The Scarcity of Unfinished Steel

A striking feature of the steel situation has been the extreme scarcity of unfinished steel. The billet and sheet bar market has pursued its own course. It increased in strength in 1915 and in the first four months of this year quite in keeping with the developments in finished steel products, but in May it turned somewhat soft and in June there were offerings that were absorbed with such difficulty that the market turned distinctly soft and prices became notably lower. In July there was some buying in the domestic market, but not a great deal, and there was a moderately heavy export demand. There was continued heavy demand for shell steel, the buying being continued for a much longer period than had been expected. Early in August unfinished steel was suddenly found to be very scarce and the mills practically withdrew from the market. Excited canvasses have been made for steel by both domestic and foreign buyers and in the past fortnight the conviction has been reached that there is practically no soft steel offered, irrespective of price, for any delivery during the remainder of the year. Billets and sheet bars are quotable at \$45 to \$50 but the quotations are nominal. Occasional buyers who have influence and trade connections may be able to secure steel but the average buyer cannot make a purchase. The market has accordingly turned very quiet.

The condition as to unfinished steel is not an ordinary market one, there being no proper relation between unfinished and finished steel. Current prices for billets and merchant bars, sheet bars and light gage sheets, do not represent spreads equal to the actual mill cost of conversion. There would be a greater profit to the steel mill in selling billets instead of merchant bars, or sheet bars instead of light gage sheets. Apparently the reason the unfinished steel is not sold instead is that the mills wish to hold their custom and must hold their organizations. If finishing operations are curtailed the men seek employment elsewhere and they could not be replaced until the next depression comes.

Pig Iron More Active

During the past fortnight the pig iron market has come to life. Several fair sized lots of Bessemer and

basic iron have been bought by large steel works, while there has been well distributed buying of foundry and malleable. The buying has been done very quietly, few general inquiries being put out, and the market has been more active than appeared from surface indications. Apparently the buyers feared that higher prices would come to prevail if more interest were shown and as prices have been well established it has not been necessary to depend upon competitive bidding to secure the lowest quotation available. It is characteristic of the pig iron market that general buying movements frequently start in August, and the only explanation for such a development in a month that is regarded in general as a dull one marketwise is that many buyers desire to get under cover before an expected rise occurs. No shortage of pig iron can be regarded as having been developed in the past two months, for while furnace outputs have been reduced by the humidity the consumption by steel mills has been reduced in greater ratio. For the future, however, the majority opinion is that pig iron is destined to grow scarcer as there is little new furnace construction while steel making capacity is being constantly increased. Pig iron prices are substantially unchanged, and indeed there has been scarcely any fluctuation since the first of the year.

While iron ore shipments down the lakes have been heavy thus far this season, fully as heavy as the highest estimates indicated, there are doubts whether the movement can continue of the same proportions. The strike of dock laborers at the head of the lakes has been settled, but the Mesabi range strike continues. Production by the underground mines is only a few per cent of capacity and Mesabi range shipments are from the open pits and from stock piles. The stock piles will hardly stand the drain to the end of the season and in some quarters the suggestion is even made that all-rail shipments may be necessary in the winter. There is demand for ore for puddling and open-hearth furnace use and occasional sales are made at premiums above the regular season prices. Some interest is already being manifested in ore for 1917 and there is talk among ore producers of advancing prices about a dollar a ton, following the advances for the present season of 70 cents on old range and 75 cents on Mesabi ores.

Non-Ferrous Metal Market

Aug. 29.—Most of the metals have become stronger during the last two weeks as the result of renewed buying, especially in copper.

Copper.—Buying by domestic consumers has made a strong market during the last two weeks and Lake and electrolytic are quoted at 27.50c. for September and October delivery. November and December is quoted at 27 to 27.25c., with January and February about 1/2c. lower. Present smelter production is estimated at from 200,000,000 to 250,000,000 lb. per month. Refinery production is somewhat less. The consumption demand in this country has lately been increasing, and is expected to grow still more. Exports up to Aug. 25 were 25,205 tons of 2240 lb.

Tin.—The tin market has not been so active as some of the others, but has had a strong undertone. Deliveries for September, October and November are hard to obtain, owing to uncertainties regarding permits. Spot tin is quoted at 38.75, with futures for next year selling at 38.25 and higher.

Lead.—Considerable strength has been evidenced in the lead market, due to local and Canadian buying. Foreign buying has not been strong, as the foreign governments are said to be well covered. The Trust price has been put back to 6.50c. New York by two

advances, one on Aug. 17 and one on Aug. 18, and independents are asking 1/4c. higher than this price.

Spelter.—The situation in spelter at present is quiet and easy. About a week ago considerable buying for export created a strong market, but since then there has been a reaction. Prompt spelter is quoted at 9.30 to 9.55c., with fourth quarter at 8.75 to 9.00. The first of the five units of the new electrolytic zinc refinery at Anaconda is completed and ready for operation. The total capacity will be 70,000,000 lb. per annum.

Other Metals.—There was considerable buying of antimony a week ago, but at present the market is dull, with Chinese and Japanese quoted at 13.25 to 13.75c. Aluminium is quoted at 61c., magnesium at \$3.75 per pound, quicksilver at \$75.00 per flask, platinum at \$60.00 per ounce, and silver at 66 1/4.

Notes on Metallurgical and Chemical Engineering in Great Britain

By our London Correspondent.

Since your issue of April 15, in which a short review of the industrial situation in Great Britain was given, probably the most outstanding feature in the industrial situation is that of the further gradual withdrawal of labor consequent on the calling up of larger groups of men for military service.

Speaking broadly this has been done without disturbance of output, the employment of female labor wherever possible permitting of the change without affecting the general situation.

The abandonment of the Whitsuntide holiday was accepted by the industrial classes in a praiseworthy manner, and a considerable saving thereby effected.

Production of machinery for what may be termed private purposes (*i.e.*, not connected with the war) has not come to a standstill, the cessation of orders being governed as much by waiting on the general situation as by the necessity of standing aside for more urgent work. The withdrawal of labor is probably felt more deeply by the building trades and those dependent on local carriage of goods, such as laundries and small retailers; it is not noticeable in engineering factories. At a pinch there are large numbers of men over military age, and youths just approaching it, who would be willing to undertake work required to set free specialized labor for any purpose of national importance.

The graduated movements of prices in the commodities on the open market is a satisfactory feature.

Attention is continually being drawn to the loss to the community of coal products by the burning of the coal in beehive ovens. Sir William Garforth in his Presidential address to the Institute of Mining Engineers, dwelt upon the need for investigation into this loss. On a conservative estimate 70,000 tons of ammonium sulphate and 12 to 15 million gallons of benzol, as well as tar, could be saved if the coal were distilled in retort ovens. The general interest directed in the direction of saving coal and coal products is a most encouraging symptom at the present time.

Bearing upon the artificial manure question, the Sulphate of Ammonia Association recently gave some interesting figures from an article in the *Frankfurter Handelsblatt* of May 29th. The Association does not, of course, vouch for the accuracy of the estimates, and considers one or two of the statements to be obviously exaggerated. The article, however, apart from this, is of interest to those who can weigh its statements. A table is first given showing the increase in consumption of nitrate of soda in Germany from 55,000 tons in 1880 to 747,000 tons in 1913. By degrees the imported ar-

ticle has been superseded by sulphate of ammonia, of which 460,000 tons were used in 1913, as against 750,000 tons of nitrate of soda. In order to have a supply of artificial manure nearer than Norway the Badische Aniline and Soda works, unable through lack of water-power to manufacture by the Norwegian process, started a process of their own, called after its originator the Haber process. Production rose from 30,000 tons in 1913 to 60,000 in 1914, and 150,000 tons by the middle of 1916. The production from 1916 onwards is estimated at 300,000 tons. The article further assumes that this output can be increased to 500,000 tons, a quantity equal to the value as manure of the nitrate of soda formerly imported.

The various results supposed to follow on the above by the writers of the article do not seem to be affected by problems of carriage and distribution.

The meeting of the British Association will be for the week following September 5, at Newcastle. The President-Elect is Sir Arthur Evans, F.R.S., who will preside over the Engineering Section.

A valuable paper was recently contributed to the proceedings of the Faraday Society by Mr. Z. Jeffries of Cleveland, Ohio, on "Grain Size Measurements in Metals and the Importance of Such Information."

* * *

Some curious fluctuations have taken place in the prices of metals during the period March-April-May. Tin in comparison with its usual habits, may be said to have been the least active. Starting early in March at £184 it climbed pretty speedily (only two slight drops) to £202 on the 28th. It then dropped to £198 by May 4, and, turning, rose rapidly to £205 on the 8th. Then came a rapid drop of £7 in four days, since which the tendency has been downward, till £187 was reached on May 31.

Considering that the fluctuations on this metal have been confined to £21 or, say 10 per cent, there seems to be nothing sensational about it. Probably the price is so near the top as to have a steadying effect.

Copper on the other hand has shown a remarkable rise in price. Starting in March at a high price £106, it dropped on the order prohibiting speculative dealings in metals of vital importance to £96 by the 9th. Recovering, however, it ran up to nearly £119 in under a fortnight, then lost £4, and ultimately settled down to a steady rise to over £145 on May 17. A rapid drop followed which had landed it at £122 by the end of the month. The total fluctuation was therefore £40, or something like 50 per cent on the normal price.

Lead has also been very active. Even at the extraordinary price of £34 with which it commenced in March, it rose to £36 by the 21st, and only had one drop, to £33 on April 5. A downward tendency commenced about the middle of April, however, which became more pronounced in May, and the metal closed at £32.

Scotch Pig and Cleveland both rose till the middle of April, when Scotch stood at 104/- and Cleveland at 96/-. The end of May saw them at 88/- and 82/- respectively.

Hematite, however, went up and remained up, being quoted throughout March at 115/- and assuming in April a nominal price of 122/-.

Quicksilver was quite steady all through, about £17 per bottle.

* * *

Signor Marconi's promise of a newly invented method of preventing collision at sea shows how the inventive mind may be engaged in its usual activities even when one would suppose it to be sufficiently loaded by the pre-occupation and urgent needs of present circumstances. While awaiting with interest the description of the apparatus it may be recalled that Professor Joby has al-

ready worked out one method which he described in his book on the subject of Marine Signalling. For shore use this method depends on the transmission of two signals, a sound and a wireless one.

The difference in the time of receiving was the basis from which knowledge of position was worked out. The collision safeguard appeared to be liable to confusion in crowded waters.

* * *

Reference was made to the export of nitrate of soda from the Norwegian fixation factories in a lecture by Mr. E. Kilburn Scott at Birmingham on June 15. He pointed out the need of stimulating the production of ammonia nitrate, and the method by which this might be accomplished.

* * *

The possibility of a shortage of copper in Central Europe inducing a large consumption of Aluminium for Electrical purposes makes a recent article in *L'Information* on the comparative outputs of the metal especially interesting. The writer estimates the combined output of works belonging to England and France at 28,000 tons per annum, and Italy 3000 tons, against 22,000 tons for Germany and Austria. Among the former are deposits at Straun in Iceland and the British Aluminium Company's sources of supply at Glenravel. France has mineral deposits at Bouches du Rhone and the Var. Germany only possesses deposits in Hessen-Nassau, the quality of which does not appear to be up to standard, but these are, of course, supplemented by Austria with products from Styria and Carniola, as well as at Prechora. Previous to the war the Germans had, apparently, been acquiring interests in a company for working the French deposits, but this company has since been placed under sequestration.

The tendency of investigation in any science to split itself into a number of different branches is again exemplified by the information gained in the study of X-rays. At the meeting of the Roentgen Society on June 6, Prof. J. W. Nicholson read a paper on homogeneity of visible radiation, in the discussion on which Major Robert Wilson pointed out that different results could be obtained by the use of rays obtained from high tension transformers than by the use of the static machine.

Dr. G. W. Kaye, going further into the subject, gave examples showing the lack of homogeneity in X-rays, which appears to open up a very large field for investigation.

Among the Societies passing resolutions for the exclusion from membership of enemy aliens are the Institution of Electrical Engineers, and the Chemical Society.

MARKET PRICES
June, 1916

	£	s	d
Borax, Brit. refined (crystal), cwt.	1	10	0
Copper sulphate, ton	53	0	0
Elegant red lb.	2	0	0
India-rubber, Para fine, lb.	2	6	5
Mica, original cases, medium	1	6	0
Quicksilver (Spanish), bottle	15	0	0
Scheemmanite, ton	75	0	0
Snellite, cwt.	1	15	0
Nitrate of soda, refined, ton	18	15	0

Copper opened at £121 and rose to £124 on the 5th, thence easier to £107 on the 20th, and £103 on the 26th.

Tin opened £189 and continued down to £183 on the 6th, then recovered to £187.15 on the 9th, but dropped again, reaching £177 on the 20th, and £173.10 on the 26th.

Lead opened £33 and hardened to £33.5, but dropped from the 9th to £32.5 on the 16th, and £30.15 on the 26th.

Cleveland has been 82/6 for home consumption and 100/- for export throughout the month.

Hematite.—No prices available.

Scotch Pig.—122/6 Home, 140/- export.

Second National Exposition of Chemical Industries

The managers of the Second National Exposition of Chemical Industries, to be held at the Grand Central Palace, during the week of Sept. 25, report that most of the space on the second floor has been taken.

To meet the requirements of the societies who will hold meetings at the Grand Central Palace the auditorium has had to be increased in size, so that now it will comfortably seat five hundred persons. An automatic motion-picture machine of the latest design will be used to display the motion pictures, many of which will be loaned by exhibitors. In many cases there will be lecturers to take the audience through a pictorial tour of a plant, and they will be shown machinery and processes in the manufacture of materials. Many of the films are at present being made, and are expected to be finished in time to be shown at the Exposition. A few of these films are as follows:

Making of Black Powder.
Manufacture of Iron.
Manufacture of Fertilizers.
Mining and Manufacturing of Iron.
Manufacturing of Silk.
Making of Blotting Paper.
Silver Mining.
Manufacturing of Varnish.
Asphalt.

Two other features of the Exposition that have been added this year are a large section showing the opportunities that await the chemist in our South, and known as the "Southern Opportunity Section," and a section for the "Paper and Pulp Industry," composed of materials and machinery used in the manufacture of paper and other related products.

The "Southern Opportunity Section" was formed to display to our chemists, chemical engineers and capitalists the great latent wealth that awaits them in the undeveloped resources of the South.

The Bureau of Mines is preparing an elaborate exhibit that will cover much space; it will be a working exhibit, one where the visitor can see actual operations being carried on.

The members of the American Chemical Society and the American Electrochemical Society who register with their societies will receive badges. These will admit them to the exposition without further tickets.

The following list comprises concerns which have taken space at the Exposition up to the time of going to press:

Abbe Engineering Company
Abbe, Paul O.
American Chemical Society
American Electrochemical Society
American Coal & By-Products Coke Company
American Institute of Mining Engineers
Angel & Company, H. Reeve
Badger & Sons Company, E. B.
Baker, J. T., Chemical Company
Barrett Company, The
Bausch & Lomb Optical Company
Benzol Products Company
Bethlehem Foundry & Machine Company
Boston Artificial Leather Company
Brown Instrument Company
Buffalo Foundry & Machine Company
Carborundum Company
Carrier Engineering Company
Celluloid Zapon Company
Codd Company, E. J.
Condensite Company of America
De Laval Separator Company
Detroit Range Boiler Company
Devine Company, J. P.
Dorr Company

Drexel Chemical Company
Dreyer-Harris-Wood Company
DuPont, E. I., De Nemours Company.
Dunham Chemical Company
Edison, Thomas A.
Eimer & Amend
Electro Bleaching Gas Company
Elyria Enamelled Products Company
Foots Mineral Company
Freeport Sulphur Company
Geissinger Regulator Company
General Bakelite Company
General Chemical Company
German-American Stoneware Company
Glens Falls Machine Works
Great Western Power Company
Greiner Company, Emil
Hardinge-Conical Mill Company
Herold China & Pottery Company
Huff Electrostatic Separator Company
International Equipment Company
International Filtration Corporation
International Glass Company
Kieselguhr Company of America
Koppers Company, H.
Koven & Bro., L. O.
Laboratory Supply Company
Lead Lined Iron Pipe Company
Leeds & Northrup Company
Lenz & Naumann, Inc.
Little, Arthur D., Inc.—Boston
Little, Arthur D., Ltd.—Montreal
Lungwitz, Emil E.
Luzerne Rubber Company
Marden, Orth & Hastings Company
Merck & Company
Metallurgical & Chemical Engineering.
Monsanto Chemical Works
Mott, J. L., Iron Works
Multi-Metal Sep. Screen Company
National Aniline & Chemical Company.
National Gum & Mica Company
Niagara Alkali Company
Norton Company
Ohio Pottery Company
Palo Company, The
Patterson-Allen Engineering Company
Ptaudler Company
Precision Instrument Company
Raritan Copper Works
Raymond Bros. Impact Pulverizer Company
Research Corporation
Ruggles-Coles Engineering Company
Schaeffer & Budenberg Manufacturing Company
Schaum & Uhlinger, Inc.
Schutte & Koerting
Scott & Company, Ernest
Scientific Materials Company
Smet-Solvay Company
Sharpley Specialty Company
Sidio Company of America
Solvay Process Company
Sowers Manufacturing Company
Squibb & Sons, E. R.
Stamford Manufacturing Company
Standard Aniline Products, Inc.
Stevens-Aylsworth Company
Sturtevant Mill Company
Sweetland Filter Press Company
Swenson Evaporator Company
Taylor Instrument Company
Technical Association of Paper & Pulp Industry
Tennessee Power Company
Thermal Syndicate, Ltd.
Thwing Instrument Company
Toch Brothers
Toihurst Machine Works
Uehling Instrument Company
Union Sulphur Company
United Lead Company
United States Smelting Company
Valley Iron Works
Weiller Manufacturing Company
Werner & Meiderer Company
West Pulverizer Machine Company
Williams Patent Crusher & Pulverizer Company
Zaremba Company

American Transformer Company
American Synthetic Color Company
Alberene Stone Company
Barber Asphalt Paving Company
Wm. Beckers Aniline & Chemical Works
The Bristol Company
Bureau of Mines
Central Foundry Company
Chemical Catalog Company
Chemical Company of America
Coatesville Boiler Works
Corning Glass Works
Cisner Electrolytic Alkali Works
J. H. Day Company
Denver Fire Clay Company
Downtown Manufacturing Company
Electro Chemical Company
Electron Chemical Company
The Foxboro Company
General Electric Company
Harrison Bros. Company
Frank Hemingway Corporation
Hooker Electrochemical Company
F. C. Huyck & Sons
Krebs Pigment & Color Company
F. Kleinschmidt & Company
Life Saving Devices Company
Lehigh Car Wheel & Axle Works
Manufacturers' Record
Mathieson Alkali Works
Mine & Smelter Supply Company

Mississippi River Power Company
 Nash Engineering Company
 Nitrogen Products Company
 Newport Chemical Works, Inc.
 Paper, Inc.
 Paper Trade Journal
 Pennsylvania Salt Manufacturing Company
 Process Engineers, Ltd.
 Pyroelectric Instrument Company
 Roessler & Hasslacher Chemical Company
 Seydel Manufacturing Company
 Stone & Webster Engineering Corporation
 Shriver & Company, T.
 Swiss Colours Company
 Stuart & Peterson Company
 Society of Chemical Industry
 United Gas Improvement Company
 U. S. Standard Chemical Works

New York Meeting of American Electrochemical Society

The thirtieth general meeting of the American Electrochemical Society which will be held in conjunction with the Exposition of Chemical Industries during the week of September 25 to 30, will be opened on Thursday, Sept. 28, with the "Made in America" technical session. The complete program of technical and business meetings and of entertainment features will be given in our next issue. The ladies' entertainment features will be found in the adjoining program of the ladies' committee. Members of the Electrochemical Society will register at the Society's booth at the Exposition. The complimentary smoker on Thursday evening and the joint banquet on Friday evening with the American Chemical Society and Technical Association of the Paper & Pulp Industry promise to be real live entertainment features. Other entertainment features will be announced later, together with the complete technical program.

Program of Ladies' Committee of American Chemical Society and American Electrochemical Society

The following program has been arranged for visiting ladies by the ladies' committee of the American Chemical Society and American Electro-Chemical Society for the New York meetings during the week of Sept. 25. The lady in charge of each event is included.

Monday and Tuesday—Welcoming the visiting ladies at the registration rooms—(Chemists' Club). Mrs. Frank Henningway.

Visiting the Chemical Industries Exposition. Mrs. Bernard C. Hesse.

Tuesday—8.00 p. m. Reception at Hotel Astor.

Wednesday—10.30 a. m. Meeting—Chemists' Club, for an automobile tour along the Hudson. Mrs. J. Merritt Matthews.

1.00 p. m. Luncheon at Longview, Hastings-on-Hudson. Return to New York 5.00 p. m. Mrs. J. Malcolm Muir.

Thursday—10.30 a. m. Meeting—Chemists' Club for a visit to Altman's and Tiffany's stores. Mrs. R. N. Shreve.

1.00 p. m. Luncheon at the Woman's City Club and at the University Club. Mrs. R. N. Shreve.

8.00 p. m. Theater party—Complimentary to visiting ladies only.

Friday—2.00 p. m. Seeing New York Yacht Party. Mrs. Charles Baskerville.

8.00 p. m. Banquet.

Saturday—Visiting Chemical Industries Exposition. Mrs. Bernard C. Hesse.

The ladies' committee, including those who have joined up to the present time is as follows: Mrs. L. H. Baekeland, in charge; Mrs. Milton C. Whitaker, Mrs. Bernhard C. Hesse, Mrs. Jerome Alexander, Mrs. Mor-

ris Loeb, Mrs. Charles Baskerville, Mrs. J. Merritt Matthews, Mrs. Parker C. McIlhiney, Mrs. Frank Hemingway, Mrs. T. B. Wagner, Mrs. Elon H. Hooker, Mrs. Charles H. Herty, Mrs. Charles L. Parsons, Mrs. Herbert R. Moody, Mrs. R. N. Shreve, Miss Leola Maars, Miss E. H. Kunz, Mrs. Maximilian Toch, Mrs. J. Malcolm Muir, Mrs. Eugene F. Roeber, Mrs. Colin G. Fink, Mrs. A. B. Marvin, Mrs. Lawrence Addicks, Miss Agnes Hasslacher, Mrs. J. V. N. Dorr.

Cleveland Meeting of American Institute of Metals

The annual meeting of the American Institute of Metals will be held in Cleveland, Sept. 11-15, together with the convention of the American Foundrymen's Association. The annual foundry exhibition will be held in the Coliseum, and indications point to a much larger exhibit than was shown at Atlantic City last year. There will be many interesting entertainment features, including a trip to the ball park Tuesday afternoon, Sept. 12, for the game between Cleveland and Detroit; a trip to Euclid Beach Park Tuesday evening in special cars, tickets being furnished to all concessions; an inspection trip Wednesday afternoon to the Cleveland Furnace Company's blast-furnace plant on the Cuyahoga River flats, and entertainment at Keith's Hippodrome Wednesday evening. A luncheon will be given the ladies at the Hotel Statler, and on a later day an automobile ride. The annual banquet will be held Thursday evening, at the Statler, with Irving Bachelier as one of the speakers. Plant visitation will be limited to Thursday and Friday. Arrangements have been made for the inspection of the plants of the Ferro Machine & Foundry Company, Allyne-Ryan Foundry Company and Westinghouse Electric & Mfg. Company.

Following is a list of some of the papers which will be presented:

"Reclamation of Metallics from the By-Products of Foundry and Manufacturing Plants," by A. F. Taggart.

"Method of Selling Non-Ferrous Scrap, as Pursued by a Large Producer," by J. M. Bateman.

"The Result of Joint Work of Casting and Testing the 88-10-2 Alloy by Five Foundries, Report of the Use of the Deoxidizers of Bronzes and Report on the Aspects of Bronze Failures," by various experts affiliated with the U. S. Bureau of Standards, Washington, D. C.

"Copper-Aluminum-Iron Alloys," by W. M. Corse.

"Tests on Rolled Brass Sheets Taken in the Direction of Rolling and at Right Angles to the Direction," by W. B. Price and P. H. Davidson.

"The Application of Oxy-Acetylene Welding Process in the Repair of Defective Non-Ferrous Castings," by S. W. Miller.

"Continuation of Discussion in Connection with Defective Bronze Castings in Use by the Board of Water Supply of New York City," by A. D. Flinn.

"Evolution of Die Casting Process," by Charles Pack.

"Disclosure of Blowholes by Means of X-Ray Apparatus," to be reported by testing engineers employed in laboratory D of the General Electric Company, Schenectady, N. Y.

"Aluminum Castings and Forgings," by P. E. McKinney.

"Annealing Properties of Copper," by G. W. Ceaser and G. C. Gerner.

"Metallography as Applied to Non-Ferrous Metals," by W. W. Arthur.

"Heat Treatment of German Silver," by G. C. Holder.

Rubber Vulcanization Accelerators

BY ANDREW H. KING

This is a subject now attracting considerable attention in the rubber business. The possibilities seem almost unlimited. For example, a factory which has been using the old, well-known mineral accelerators can materially increase its capacity by the use of some one or more of the new organic catalysers, such as piperidine or para-phenylenediamine.

It is common knowledge that the degree of vulcanization can be greatly influenced by a change in either time or temperature. Thus a stock which cures ordinarily in 40 minutes at 40 lb. steam pressure can be vulcanized in 25 minutes at 60 lb. This is one way to speed up production. However, the increase in working steam pressure is expensive, and sometimes quite unsatisfactory. It is far better to add from 1 to 2 per cent of some good accelerator, and properly cure the rubber at low pressure, than to run chances of injuring the nerve by high temperature. In certain instances both high temperatures and accelerators are used, as in the case of cheap molded goods, where a large production is necessary to take care of the overhead.

An accelerator is merely a catalyser. It tends to increase the velocity of the reaction between sulfur and rubber during vulcanization. For the sake of clearness, I will enumerate a few conclusions deduced from numerous observations of the catalytic effect, sometimes called "the laws of catalysis":

1. The catalyser has the same chemical composition at the end of the reaction as it had in the beginning. This statement applies to nearly all accelerators, except certain of the organic compounds which are decomposed to a more or less extent at the temperature of vulcanization.

2. A catalytic agent is incapable of starting a reaction. It can only modify the velocity.

3. Very small quantities are sufficient to transform relatively large amounts of reacting substances.

4. The final state of equilibrium is independent of the nature and quantity of a catalyst.

5. Catalysers are of two kinds—positive and negative; i.e., they may either increase or retard the reaction velocity.

The above statements are based on observed facts. Just why they are so, and what the underlying principle of catalysis is, the future may explain. There are numerous theories which seem to fit separate cases quite well. Thus, the theory of surface concentration seems an excellent explanation of the behavior of platinum sponge in the contact process for sulfuric acid.

But the separate group of vulcanization accelerators seem to belong to the intermediate product family. It is thought that the catalyser unites with one of the reacting substances, forming an unstable compound, which in turn reacts with the other substance. In the course of this reaction, the catalyser is set free, and the process begins all over again.

An example of this phenomenon, though not a catalytic action in the true sense, is found in the commercial method for the preparation of aniline. Nitrobenzene is reduced by means of iron filings and hydrochloric acid. Only about one-fortieth of the theoretical quantity of acid is necessary. This is probably because iron filings and water are able to effect the reduction in the presence of ferrous chloride. In this instance it may be called a pseudo-catalyser. The reactions taking place are sometimes written as follows:

The halogen carriers, which are so important in organic preparations, are also pseudo-catalysers.

The chemical reaction between sulfur and rubber may be written:

The speed of this reaction is influenced in proportion to the quantity of accelerator used, up to a certain limit, beyond which it acts as a retarder; that is, as a negative catalyser. As a general rule, accelerators should be used in small amounts, so as not to affect the nerve or quality of the rubber.

A peculiar fact has been noted. By a combination of accelerators the resulting increase in speed is greater than the sum of their individual increases, when acting alone. For example, the effect of 1 per cent tetramethylenediamine and 1 per cent piperidine exceeds the sum of the effects of the same catalysers when mixed in separate batches.

MINERAL ACCELERATORS

The chief mineral accelerators are:

Lime
Magnesia
Litharge
White lead
Zinc oxide

They are named in the order of their relative power.

Lime: The lime in common use is prepared by burning limestone and slacking the product by means of steam. Properly prepared, it is just a little short of complete hydration. In curing soft rubber from 1/2 to 2 1/2 per cent may be used. For hard rubber larger amounts are customary.

Magnesia: The best magnesia is a heavy calcined product known as "Magnesia Usta." It is prepared by precipitating magnesium from solution in the form of magnesium carbonate and calcining the product. Magnesia finds a larger use than lime, though its curing action is only about half as great. Its advantage is that it leaves the nerve of the rubber absolutely unaffected, while lime has a slight hardening action. Combined with litharge it produces very satisfactory results.

Litharge and other lead compounds: Besides litharge, such compounds as white lead, sublimed white lead, and red lead are also valuable. Their use is limited, however, to black goods, and to those having high specific gravities. Stevens (J. Soc. Chem. Ind., 34, 524-6, 1915) is of the opinion that the catalytic effect of litharge is due to the heat liberated by the following reaction:

This effect is proportional to the quantity present, so long as there is sufficient sulfur available to properly cure the rubber, and to convert the litharge to lead sulfide and sulfate. About 1 per cent sulfur is required for every 7 per cent of litharge. At the point where the rubber is fully cured the free sulfur drops, but is never completely absent. Large amounts of litharge serve to prevent "blooming"; i.e., the coming to the surface of colloidal free sulfur in the form of a gray scum.

Red lead is more active than litharge, but should never be used because of its oxidizing tendency. White lead, that is basic lead carbonate, is also an accelerator. Compared with litharge it has a much lower specific gravity and considerable toughening action. Sublimed white lead has the following average composition:

PbSO ₄	78.5%
PbO	16.
ZnO	5.5

It has only slight curing action, but is also a good toughener.

Zinc oxide: This has but little accelerating power. As a toughener it surpasses all of the lead fillers, and is only exceeded in this respect by lamp black. Because of its slight catalytic effect, considerable quantities can be used without retarding the cure.

Miscellaneous: Some oxides have a catalytic action under special circumstances. Thus, iron oxide (3 to 8 per cent) is quite useful in batches containing brown substitute.

Golden antimony sulfide also finds considerable use. It has but small catalytic value. Its action is due mainly to free sulfur, which the technical product always contains.

Manganese oxide, MnO , and cuprous oxide, Cu_2O , are both good accelerators, but because of their marked oxidizing tendencies they cannot be used. In fact, as a general rule copper and manganese, in any form, must be kept out of rubber if the product is to be anything but worthless.

Molybdenum sesqui-oxide over 10 per cent and alkali over 3 per cent are negative accelerators. The behavior of alkali is especially interesting, owing to the extensive use of alkali shoddies. Up to $\frac{1}{2}$ per cent it acts as an accelerator. Beyond this it retards, and at 5 per cent it is almost impossible to effect a cure. Nickel oxide is a negative accelerator, and vulcanization can be entirely prevented by its use.

ORGANIC ACCELERATORS

The use of organic accelerators dates from the discovery of synthetic rubber. This product cannot be vulcanized without the addition of some of the organic catalysts. On the substitution of natural for synthetic rubber equally successful results were obtained.

The trouble with synthetic rubber, and for a time with the plantation variety, was excessive cleanliness. They secured the rubber hydrocarbon, but certain so-called impurities, which Mother Nature places in the rubber latex, were carefully excluded. Para rubber, by the Amazon method of coagulation, contains all the elements of the latex evenly distributed throughout the mass. For this very reason it is still true that no rubber is the equal of Highlands Fine Para.

The catalysts present in rubber latex are thought to be related to the proteins, perhaps decomposition products. All organic accelerators are nitrogen bearing, and many have amino groups. The function of the nitrogen seems very important. So far there are only two generalizations possible:

1. According to Dittmar, all organic bases having dissociation constants greater than 10^{-4} act as accelerators, irrespective of constitution.

2. At present only nitrogen bearing compounds are known as accelerators, and it seems that this element must be a necessity.

From a mechanical standpoint a catalyzer is most conveniently mixed when it has the following properties:

It should be a solid, capable of being very finely pulverized.

It should have a high boiling point, so as not to be vaporized during vulcanization. Such behavior would cause a spongy appearance; that is, "blowing."

For convenience I will classify the most important organic accelerators under the following heads:

1. Carbon bisulfide addition products with

- (a) Aniline
- (b) Dimethyl aniline
- (c) Tetrahydropyrrole
- (d) Dimethylamine

2. Ammonium compounds

- (a) Ammonium borate
- (b) Aldehyde ammonia
- (c) Quaternary ammonium bases

3. Amino compounds

- (a) Para-phenylenediamine
- (b) Tetramethylenediamine
- (c) Sodium amide
- (d) Naphthylene diamine
- (e) BB Dimethyl Δ methyltrimethyleneimine
- (f) Trimethylenamine
- (g) Benzylamine

4. Piperidine and derivatives

- (a) Piperidine
- (b) Methyl piperidine

5. Quinoline and derivatives

- (a) Quinoline
- (b) Quinoline sulfate
- (c) Quinisol
- (d) Sulfuroxyquinoline

6. Miscellaneous

- (a) Anthraquinone
- (b) Urea derivatives
- (c) Formanilides

CARBON BISULFIDE ADDITION PRODUCTS

With Aniline: One of the oldest accelerators known in this country is diphenylthiourea, or thiocarbamide,

This substance may be prepared according to Gatterman as follows:

A mixture of 40 parts aniline, 50 parts carbon bisulfide, 50 parts of alcohol, and 10 parts of finely powdered potassium hydroxide are boiled gently on a water bath for three hours in a flask provided with a reflux condenser. Excess carbon bisulfide and alcohol are distilled off, and the residue treated with water. The crystals separating out are filtered off, washed first with water, then with dilute hydrochloric acid, and finally with water. To obtain the pure substance, recrystallization from alcohol is necessary. Large colorless tablets are obtained, which melt at 154 deg. C. A very satisfactory, and, in fact, a more desirable, product for use as an accelerator is secured by the substitution of sodium polysulfide Na_2S_x for caustic potash in the above reaction. A high degree of purification is unnecessary. At some factories the aniline, carbon bisulfide, and sodium polysulfide are mixed in large kettles in the open air. After a short time the whole mass solidifies. This is broken up, vacuum dried, and finely ground. A fairly satisfactory product is thus secured. The reaction taking place in this preparation may be written as follows:

This substance is a very efficient catalyzer. It seems to do all of its work at the beginning of the reaction, so that it finds considerable use in quick curing stocks. One-half to 3 per cent is customary.

With Dimethyl Aniline: Carbon bisulfide also forms an addition product with this substance. The reaction here is similar to that of aniline.

With Tetrahydropyrrole: This substance $(\text{CH}_2)_4\text{NH}$, called by the German chemists "pyrrolidin," is secured

by the reduction of pyrrole, C_4H_5N , by means of zinc dust and hydrochloric acid. Pyrrole is closely related to the proteins, and its derivatives have been isolated from protein decomposition products. The reactions for the preparation of the addition product may be indicated as follows:

With *Dimethylamine*: As would be suspected, dimethyl amine, $(\text{CH}_3)_2\text{NH}$, gives an active addition product, whose constitution may be written:

AMMONIUM COMPOUNDS

Ammonium Borate: *Ditmar* (*Gummi Zeitung*, Jan., 1915) mentions the fact that ammonium borate has a noticeable effect on the cure. This is merely of scientific interest.

Aldehyde Ammonia: This is a very satisfactory catalyser. A mixture of 100 parts Para, 10 parts sulfur, and 1 part aldehyde ammonia may be cured in 30 minutes at 45 lb. steam pressure (140 deg. C.). For comparison, a batch of 90 parts Para, 9 of sulfur, and 1 of lime requires 85 minutes at 140 deg. C.

Aldehyde ammonia, $\text{CH}_3\text{CH}(\text{OH})\text{NH}_2$, is best prepared by passing dry ammonia gas into a solution of acid aldehyde, CH_3CHO in ether. The reaction is as follows:

It is readily soluble in water, sparingly so in alcohol, and almost insoluble in ether. It melts between 70 and 80 deg. C., and sublimes without decomposition at 100 deg. C.

Quaternary Ammonium bases: These are mentioned in Bayer & Co.'s British patent 12,661 of May 22, 1914, along with aldehyde ammonia, para-phenylenediamine, sodium amide, benzylamine, and naphthylenediamine.

AMINO COMPOUNDS

Para-phenylenediamine: This accelerator gives good results with synthetic rubber. Bayer & Co. mention in their German patent 280,198, Jan. 1, 1914, that 100 parts isoprene rubber completely cures when mixed with 10 parts sulfur and 2 parts para-phenylenediamine and is heated in a press for 15 minutes at 45 lb. steam pressure.

Para-phenylenediamine, $\text{C}_6\text{H}_4(\text{NH}_2)_2$;  is pro-

duced by reduction of para-nitrobenzene, para-nitroaniline, or of aminoazobenzene with tin and hydrochloric acid. Other methods are: By the distillation of diamino benzoic acid. By the action of para-chloraniline on aqueous ammonia in the presence of copper salts.

Perhaps the simplest method is that for reducing aminoazobenzene. The reactions for its preparation from aniline follow:

This method is the most satisfactory, and relatively cheap. Gatterman may be followed for the preparation of aminoazobenzene. After reduction, distill off the aniline with steam. The product may be purified by fractional crystallization. Pure para-phenylenediamine melts at 140 deg. C., sublimes without decomposition at 267 deg. C., is very soluble in alcohol and ether, and moderately so in water. Manganese dioxide and sulfuric acid convert it to quinone, $\text{C}_6\text{H}_4\text{O}_2$. On passing hydrogen sulfide through a solution of the chloride, and then adding ferric chloride, thionine or Lauth's violet is produced. These tests will indicate the purity of the commercial article.

It should be mentioned that para-phenylenediamine, as likewise most organic accelerators, is very poisonous, and proper precautions should be taken in every case.

Tetramethylenediamine: This substance is mentioned in French patent 464,533 by Bayer & Co. It gives very good results when the desired time of cure is rather long.

Tetramethylenediamine, $\text{NH}_2(\text{CH}_2)_4\text{NH}_2$, called sometimes putrescine, is a natural product of protein decomposition, and is produced during the putrefaction of animal matter, such as flesh.

Dimethylene bromide, $\text{Br} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{Br}$, is converted by treatment with potassium cyanide to dimethylene cyanide, $\text{NC} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CN}$. On reducing this substance with sodium and boiling alcohol or by electrolytic methods, tetramethylene diamine is secured.

The crystals melt at 270 deg. C. and boil at 157 deg. C.

Miscellaneous Amines: Sodium amide, NaNH_2 ; naphthylenediamine, $\text{C}_{10}\text{H}_8(\text{NH}_2)_2$; trimethylene amine, $(\text{CH}_2)_3\text{N}$; benzyl amine, $\text{C}_6\text{H}_5 \cdot \text{CH}_2 \cdot \text{NH}_2$; β dimethyl Δ trimethylenimine; and nitrosodimethyl animethylamine are mentioned as having some accelerating power.

PIPERIDINE AND DERIVATIVES

The first patent granted for an organic accelerator was to Bayer & Co. (German patent 265,221, Nov. 16, 1912) for the use of piperidine. As above mentioned, it was intended to be used with synthetic rubber, but proved so successful that it was tried with the natural variety. A mixture of 100 parts Para, 10 parts of sulfur, $\frac{1}{2}$ part piperidine, is perfectly cured on heating for 15 minutes at 53 lb. steam pressure. Without the accelerator over an hour is required. Piperidine is valuable for both hard and soft rubber articles.

Piperidine, $\text{C}_4\text{H}_9\text{NH}$, belongs to the class of secondary amines. It is a liquid smelling like pepper and ammonia. It boils at 105.7 deg. C., and has a specific gravity of .881 at 0 deg. C. It is miscible with water in all

proportions. It is best prepared by reduction from pyridine, either by use of sodium in absolute alcohol or by electrolytic methods (E. Merck, English Pat. 21,471). The reaction is as given on the preceding page.

Methyl piperidine: This substance, $C_7H_{15}N(CH_3)$, is also active as a catalyst. It may be prepared by treating piperidine with methyl iodide, when the amino hydrogen is replaced by the methyl group.

Methyl piperidine is also a liquid, and boils at 107 deg. C.

QUINOLINE AND DERIVATIVES

Quinoline and its derivatives are satisfactory accelerators. The amount used varies around 2 or 3 per cent. Perhaps its sulfate and quinosol find the greater application owing to ease of mixing.

as a combination of a benzene and pyridine ring. It is most satisfactorily prepared by Skraup's synthesis; to a mixture of 19 parts aniline, 12 parts nitrobenzene and 60 parts glycerol; 50 parts of concentrated sulfuric acid are added. Heat under a reflux condenser until reaction begins. Discontinue. When the energetic reaction is over, heat on the water bath for three hours. Cool, dilute with water, steam distill to remove any unchanged nitrobenzene. Make alkaline, steam distill off the liberated quinoline and any unchanged aniline. Considerable of the aniline can be removed by fractional distillation. The remainder is removed by diazotizing in sulfuric acid solution and boiling. This converts the aniline to phenol, thus:

Quinoline, being a tertiary amine, is not affected. On making alkaline phenol goes into solution, and quinoline is liberated. It can now be removed by steam distillation, after which it is fractionated in order to obtain the pure substance. The reaction for the production of quinoline is sometimes written as follows:

The oxygen required is supplied by nitrobenzene in a manner not quite clear.

Quinoline, sometimes written C_9H_7N , $\begin{array}{c} CH:CH \\ | \quad | \\ N \quad CH \end{array}$ has a sp. gr. of 1.0947 at 20 deg. C. It boils at 240 deg. C., is soluble in alcohol and ether, but only sparingly so in water. It has a disagreeable, penetrating odor, a bitter, acrid taste, and on exposure to moist air is converted

to the hydrate, $C_9H_7N + 1\frac{1}{2}H_2O$. The nomenclature of quinoline derivatives is indicated by the scheme

Quinoline sulfate: This is sometimes called quinoline sulfonic acid. For this purpose the 8-acid is most commonly used. It is secured on heating with concentrated sulfuric acid at 220 to 230 deg. C. for a short time. Perhaps the potassium salt of this acid would give better results.

Hydroxy quinoline: This quinoline derivative should be valuable as an accelerator. It may be prepared by the fusion of the 8-quinoline sulfonic acid with caustic potash. It forms prismatic needles melting at 76 deg. C., and boils at 266.6 deg. C. under 752 mm. pressure. It is sparingly soluble in cold water, readily so in alcohol, and volatile with steam. Aqueous solutions of its acid and alkali salts are yellow.

Quinosol: This is 8-hydroxy quinoline, 5-sulfonic acid, and is prepared by sulfonating 8-hydroxy quinoline with cool, fuming sulfuric acid. (Claus and Posset, J. pr. Chem. 1890, 2, 41, 33). Thorpe (Dict. App. Chem. vol. IV, 471) prepares it by heating 8-hydroxy quinoline in alcoholic solution with potassium pyrosulfate, $K_2S_2O_8$. Quinosol forms small sulfur yellow needles, melting 175 to 177.50 deg. C. It is soluble in alcohol and in water.

Ditmar mentions oxyquinoline sulfide as a very satisfactory accelerator.

MISCELLANEOUS

Anthraquinone, 3 to 5 per cent is recommended for use in batches containing substitute.

Urea and such derivatives as guanidine are advised.

There are numerous patents covering the various anilides, such as formanilide, etc. Formanilide, $C_6H_5 \cdot NH \cdot CH : O$, is prepared from aniline and formic acid. On treatment with diphosphoropentasulfide, P_2S_5 , thioformanilide is produced, $C_6H_5 \cdot NH \cdot CH : S$.

Albumen: An interesting consideration is the patent of W. Esch (German patent 273,482, Nov. 22, 1912), which covers the direct addition of proteins to rubber. He first prepares a paste by mixing the protein, usually egg albumen, 15 parts, with 2 parts hydrated lime or magnesium hydroxide. This paste is mixed with the rubber, dried, sheeted, and smoked, to render the albumen insoluble. Low-grades are considerably improved.

CONCLUSION

To the casual reader this paper must appear rather rambling. I have only been able to touch the high spots in the subject of accelerators. In fact, only the high spots are known. As is customary with most great advances, the untrained investigator tries everything he can possibly think of. The theoretical man follows in his path, and adds his discoveries to the great mass of accumulated facts called "Science." The whole subject of rubber is one demanding scientific treatment. The velocity of the reaction between sulfur and rubber should be investigated more thoroughly and from the standpoint of the physical chemist. In fact, a consideration of this subject along the line of the phase rule would doubtless prove as valuable here as it did in the steel industry.

To the novice in this field patience is most necessary. No substance should be rejected until it has been tried under all possible conditions, and in all possible variations. In this, as in other lines of scientific research, the motto must always be, "Go as far as you can see, and then see how far you can go."

Commercial Considerations Concerning the Blast Furnace

BY J. E. JOHNSON, JR.

The object of operating a blast furnace is to make money. This obvious fact should not require to be stated but as a matter of fact for various reasons it is sometimes apparently forgotten by those who operate, and even more frequently by those who build blast furnaces. There seems to be a certain fascination about the business which inspires in those who are not familiar with it the desire to enter it and were this not balanced by an even more acute desire on the part of many of those who are in to get out, the business would be overcrowded worse than it is.

Under these conditions it seems desirable to set forth something of the commercial considerations which must govern in the long run, not only for the benefit of the owner or investor, but equally for the higher employees, for if the business is not fundamentally sound they will have an unhappy time and very likely lose the ultimate benefits of many years of hard work.

Location

This is a subject concerning which much has been written and sometimes without consideration of all the factors. There is probably no other large business in which freight on raw materials and finished product plays so great a part. It may be doubted whether freight is less than 25 per cent of the total cost delivered to the consumer except in a small percentage of the business, it is frequently more than 33 per cent and even 50 per cent. Under such conditions the question of location in relation to sources of raw materials and markets is vital.

In the "Engineering and Mining Journal" of March 13, 1915, I treated this subject on lines which are believed to be new, and developed the law on which the location of the industry seems to hinge, for it accounts for the facts as no other law seems to do. This article is quoted below.

"The reasons generally assigned for the location of the iron industry have dealt chiefly with the question of whether the ore, of which about two tons are required per ton of iron, should be brought to the coal, of which about $1\frac{1}{2}$ tons are required, or vice versa. The coal is frequently coked before shipment and the weight of coke required is only about one ton per ton of iron against nearly twice as much for the ore; but many plants have been located much closer to the coal than the ore, nevertheless. This fact has not unnaturally troubled many who have attempted to work out the underlying causes.

"It may be freely admitted that the location of iron-manufacturing centers is a matter of freight charges; but not, as is commonly assumed, of freight on raw material only. Obviously there must be included freight on the finished product to the point of consumption. If we were to consider the establishment of an iron works in a country entirely without such works, knew that each person would consume a given weight of iron per year, and knew also the tonnage of the proposed works, we should know how much population was required to consume the product and from the density of the population in the country we could calculate the average distance the product would have to be hauled to reach the consumer, and the freight for this haul added to the freight on the raw materials would constitute the total freight charge on the product. It is this which should be kept a minimum. It would clearly be an accident if the point which gave the lowest combined value

for the three were at either the ore mines or the coal mines.

"The correct location would obviously be the equilibrium point of the three forces acting through the coal mines and the ore mines and the center of population. We could, without much trouble, make a model which would illustrate the action almost perfectly. We need only to put a peg at the center of population on the map of a given district and one each at the ore mines and coal mines, fasten together at one end three pieces of rubber cord of equal length, whose strengths were proportional to the rate of freight per mile of the quantity of material equivalent to a ton of finished product, and attach the free ends to the corresponding pegs; the junction point would be the equilibrium point and would indicate the proper location of the plant. The strength of the forces acting is profoundly affected by the means of transportation available (whether water or rail) and the location of the equilibrium point is obviously influenced to correspond. The sum of the tensions in all three strings measures the disadvantage under which the district must labor.

"We can see this law demonstrated in the growth of our iron-producing centers. At the time of the Civil War, Pittsburgh was nearly the center of population of the country, and it made, for the next twenty years, the vast bulk of the steel produced, although there was a considerable center in eastern Pennsylvania and New Jersey, in which the fuel, the ore and the consuming population, were all close together and the sum of the tensions was small, so it prospered.

"As the West became settled, the center of population traveled West, first to Ohio, then to Indiana, and then to Illinois, where it is now; simultaneously the Chicago district developed as an iron center although its freight on ore is but little less than to Cleveland and Buffalo while its freight on coal is very much higher; but it is the center of a great consuming district, and its freight on finished product is low enough to make the sum of the string tensions small.

"Later still, Colorado became an iron-producing center, in spite of many disadvantages, because of its location near the center of a consuming district which is far removed from any other source of supply. The sum of its string tensions was high but that of any other iron-producing district is higher in its territory.

"The present construction of a steel plant in Duluth is a further example: The freight on both coal and ore assembled there has been very low for many years; but until the population of the Northwest became large enough to support railroads whose tonnage of steel consumption runs into six or seven figures, it did not pay to build a steel plant there. The freight on the finished product to points of consumption would have been too high.

"At Birmingham the conditions are similar but more marked. The ore and coal are in closer proximity than anywhere else in the known world, the tension in these two strings is almost nothing but the freight to outside consuming centers was so great as more than to counter-balance this advantage; the tension in the single string was more than that of all three at other iron-producing centers and the district made much pig iron but very little money until a local consuming center was built up.

"In the future, the attraction of the center of population will be increased even over what it is now; because the gas, which is a by-product in the production of coke, is of vast value for public heating and lighting and the power which can be produced with surplus gas from the furnace will be increasingly valuable for public utility purposes.

"These products are consumed in steel mills in greater quantity than they are produced by its coke ovens and furnaces, so such works are not to be considered as sources of supply for these products and their location will not be so strongly affected; but the merchant furnace will have gas and power for sale and will more and more be so located that it can dispose of them to good advantage without building long pipe or transmission lines; that is, near centers of population."

"That is, in the future, as we grow more efficient there should be an intimate connection between the iron blast-furnace plant and the public utility, and especially the public utility serving large centers of population."

Careful consideration of the history of the iron business in relation to its location will show that a plant must be located in harmony with this general law in order to have a chance of ultimate success. The importance of the by-product oven in relation to the location of the iron industry may well be a little more elaborated.

Large communities use gas in great quantities and are destined to use it in still greater ones as better processes make gas cheaper and so increase its great advantages for cooking and heating. Its use will also grow with the development of the mantle-light (Welsbach) with pilot flame control giving the convenience of electricity with a source of light as powerful and much more agreeable to many. The candlepower of gas, so important in the days of the open flame burner, is rapidly vanishing as an important consideration on account of the vastly greater amount of light which may be obtained even with a perfectly non-luminous gas, by means of the incandescent mantle.

The by-product oven yields a large quantity of cheap gas of low illuminating, but high calorific, power even after the recovery of the by-products from it, and on this account it is destined more and more to be the source of domestic gas, and this will mean the production in the vicinity of large communities of large quantities of metallurgical coke which being produced as a by-product, will be available at lower prices than an equal grade would command in that location under different conditions.

Where the community is large enough and is a manufacturing one a market for iron will exist and this will lead to the local production of iron in cases where it would be commercially impossible without these favorable conditions.

Construction

Granting that a suitable location has been chosen the size and construction of the plant next demand careful consideration. The most economical furnace to build and to run on the basis of cost per ton is the large furnace, 22 by 90 ft., if there be a market for its product when run continuously. On the other hand, almost any furnace run continuously makes cheaper iron than one run interruptedly, for the advantage of the large furnace has often been overestimated while the disadvantages of interrupted operation, both technically and commercially can scarcely be overestimated, and it is far better to build a furnace of moderate or even small size and keep it operating continuously, than it is to build a large one and run it intermittently. Some approximate figures of the difference in cost of operation of different sized furnaces will be given later.

When the size of furnace to suit the conditions has been decided many questions as to types of construction remain to be decided, and errors are often made in the decision apparently for lack of a guiding principle.

There is often a disregard of cost. Furnaces are built in the prevailing style whether that style was developed

for their conditions or not, and without any regard to whether some simpler or less expensive construction would answer. Gas engines are suggested for isolated furnaces with no market for surplus power. Trestles are built 40 and 50 ft. high and then no use made of the storage capacity so created. Bins are constructed so as to give only half the capacity they might have with the same expense. Elaborate coal and ash handling systems are applied to boilers that should properly be fired with gas 95 per cent of the time.

On the other hand, the directors are frequently "penny-wise and pound-foolish." In one case within my own knowledge they insisted on building a new furnace of scrap plate and using an old mantle and columns which necessitated the use of lines for the furnace absolutely unsuited to the conditions under which it had to work. The total saving as compared with building a furnace of new material suited to its work was \$10,000. The furnace never did what it was designed to do by a large percentage; the loss per year, due to bad furnace work, was probably not less than \$25,000, and at the end of a few years, due to the combination of rotten material and bad lines, the stack fell down bodily in full operation causing a loss of \$40,000 to \$60,000. Many other instances might be mentioned, none so bad perhaps as this but equally as stupid.

The simple rule by which the value of any construction may be measured is: Find what interest it will pay, indirectly as well as directly upon the investment. There are plenty of justifiable expenditures on which no direct saving can be shown. For instance, to build a modern hearth jacket with water-cooled staves inside a massive steel shell costs several thousand dollars more than to build one of some other types, and one of the latter might go through a blast without a breakout, in which case the return on the money spent for the better one would be nil. But again with the old type during a blast there might be half a dozen breakouts, each of which might cost as much as the increased cost of the safe construction, with the possibility that the explosions which frequently accompany breakouts might kill one or more men. In such a case it is not only foolish but almost criminal to refuse to make the expenditure which practically makes such things impossible.

In the matter of making expenditures to prevent objectionable occurrences which might shut down the furnace it is necessary to remember that certain charges which in operation we spread over the cost of the iron made, run on just the same when the furnace is shut down for repairs. When there is no iron being made to carry them therefore we can truthfully say, however it may sound, "We lose the labor and overhead on all the iron we don't make."

These charges on a 500-ton furnace run from \$1.25 to \$1.50 per ton, therefore, a twenty-four hour shut-down on such a furnace means a dead loss, exclusive of profits not made, of \$600 to \$750. This does not include the coke for banking and restoring the furnace to normal operation, or labor for repairs other than that of the regular crew. On this basis it is obvious that to spend \$5,000 to prevent a twenty-four-hour shut-down once a month would be a virtual necessity, whereas to spend the same sum to prevent such a shut-down once a year would be open to discussion.

Sometimes it is necessary to estimate what is the probability that a given mishap will occur and on the basis of that probability figure what expenditure is justified to eliminate the possibility of its occurrence.

When it comes to savings whose value per ton can be definitely estimated we are, of course on much surer ground. We have only to estimate the saving per year and compare the amount with the investment required.

Even here certain precautions are necessary. Such investments are not like the purchase of a bond in which the principal is secure and a low return is acceptable.

It is obvious that the return on such an improvement must not be less than that expected from the plant as a whole and as this is never less than fifteen and should be 20 per cent for so irregular a business, it is a safe rule to consider very thoroughly any proposed improvement which will not pay for itself in five years.

Costs

Before entering upon any further discussion of commercial considerations we must have a measure of commercial results of which the most important part is the cost sheet. Cost sheets for pig iron are very simple and are virtually standard. Like all other industrial cost sheets those of pig iron are made up of three items, raw materials, labor, and overhead, but unlike most other products raw materials are far and away more important than both the others put together, and overhead is larger in good plants than labor.

Owing to the fact that the cost of raw materials is fixed by conditions over which the management has no control and that the quantities of each required per ton of iron is subject only to a very limited control, there has come into use a standard of comparisons for costs which consists of the total cost minus the cost of raw materials. This is known as "net cost above materials." This embraces labor, minor supplies, lubricants, relining fund, renewal fund, insurance, taxes, etc. The whole amount varies from \$1.25 per ton for large and well run plants to \$2.25 for smaller or poorly run ones.

Labor varies from forty to sixty cents on a large mechanically handled furnace, to \$1.50 for small hand-operated furnaces. The relining fund must be such an amount that at the end of the blast it will equal two to three times the cost of brick for a new lining. Twenty cents per ton on a 500-ton furnace for a campaign of two years, or say 700 days, is \$70,000, which is about three times the cost of a lining for such a furnace. The renewal and repair fund should equal an amount in fifteen years that will rebuild the plant complete except site, as it will practically all wear out or be replaced in that time, and no profit can be properly shown until this depreciation be provided for.

A typical cost sheet without too much sub-division is shown below in Table I. It will be noted that no interest on the investment is shown. This is probably not correct accounting, but is universal practice in blast furnace costs. The fact should not be forgotten in considering the profit and loss shown by any blast furnace operation.

The Most Economical Size and Rate of Driving for Furnaces

As regards the consumption of ore and stone per ton of iron there is no difference between the smallest and the largest size of furnaces using the same material. In regard to coke it might be thought that the large furnace had the advantage due to less radiation and water cooling in proportion to its output, but as a matter of fact small furnaces working under the same conditions otherwise do as well as large ones and have often done much better. The better control of the charging due to their smaller size seems to offset the advantage of smaller heat losses from the larger ones.

We can therefore consider the cost of different-size furnaces only as affected by labor cost, interest and depreciation charges, and power cost.

It is not possible to obtain sufficient information for an absolutely correct solution of the question, but by

TABLE I—Cost Sheet for a Typical Blast Furnace, Based on 1914 Output

Items of Cost	Pounds	Rate Per Gross Ton	Cost per Ton
Ore	4,244	3.56	15.10
Cinder	122	2.77	0.56
Total ore and cinder.....	4,244		6.59
Scrap used	122	6.00	0.327
Gross metallic mixture.....	4,366		6.917
Total scrap purchased.....	115	6.00	
Net metallic mixture.....	4,251		6.609
Coke (net tons).....	3,392	3.10	3.74
Coal	1,133	0.80	.405

Tons produced			76,432
Daily average production.....			618
Production since relining.....			276,739

the use of certain reasonable assumptions we can make some illuminating comparisons. In regard to labor we know that there is a certain irreducible minimum no matter how small the furnace or the tonnage produced, and that an increased tonnage does not require a proportionately increased amount of labor. For instance, the size of the cast house crew does not increase very much between 200 tons and 500 tons output. On the other hand the labor of unloading raw materials from the cars is practically proportional to the amount of raw material. The engine and boiler house crew is only one man per shift for a 100-ton plant but with water tenders, extra oilers, etc., is two or three men in a plant of 500-ton output.

Generally, we may say that the labor for any output is the irreducible minimum for minimum output and for each increase in output an additional amount which increases at a slower rate than the tonnage.

Virtually the same thing is true as to plant cost and fixed charges thereon.

To build a furnace stack of a certain size and the hoist for it, costs the same irrespective of the tonnage to be produced, while the cost of the stoves for large tonnage is more than for small, but not proportionately more. The cost of bins is, however, nearly proportionate to the tonnage to be handled. The cost of the power plant is left out entirely here, because the charges on it are included in the cost of power.

We have seen in the article on the rate of driving that it is easy to obtain a reasonable approximation to the power required to blow any furnace at a given rate and knowing this we can calculate the cost of the plant very simply at so much per horsepower, or what is simpler still, knowing by the experience of various investigators, C. J. Bacon, H. J. Freyn, etc., what is the cost of power development at furnace plants, including fixed

FIG. 1—EFFECT OF INCREASED PRODUCTION ON SUM OF LABOR AND CAPITAL CHARGES — COST OF POWER FOR BLOWING AT .25C. PER HP.-HOUR AND VALUE OF SAME AT 0.50C. FOR 20 X 80 FURNACE

charges, upkeep, labor, lubricants, etc., we can use figures based on their work.

We have, however, two conditions, that where there is a market for surplus power, and that where there is none. In the last case we need consider only what power costs without any allowance for the value of the gas, and in the other, what it is worth or might reasonably be sold for. I have taken $\frac{1}{4}$ cent per horsepower hour for the first, and $\frac{1}{2}$ cent for the second, the latter being a very conservative figure.

The value of the three items, labor, fixed charges and blowing cost, in cents per ton on the basis of the assumptions made is shown by Fig. 1 for a furnace 80 x 20. The first two items are of the same character, a fixed amount plus an amount increasing with, but more slowly than the tonnage, and these are therefore added together and their sum per ton of iron shown as one curve, a hyperbola descending to the right. The curves of power cost and power value ascend almost along straight lines to the right. The sum of the former and that one of the two latter which corresponds to the conditions, shows the sum of these costs for these conditions.

These have been calculated for four sizes of furnaces, 17½ ft. x 70 ft., 20 ft. x 80 ft. and 22½ ft. x 90 ft. and 25 ft. x 100 ft., both for power cost and power value.

These are plotted on a common basis of daily tonnage in Fig. 2. The solid lines show power value and the dotted lines show power cost in each case.

Several facts show forth very clearly, first, that each curve has a minimum value or point at which the furnace will produce the cheapest iron on the basis of these costs; second, that the cost of the 17½-ft. x 70-ft. furnace is hopelessly higher than that of the 20-ft. x 80-ft., but that the latter is only a little higher than that of the 22½-ft. x 90-ft., and higher than the 25 x 100-ft. by only two or three cents per ton.

In other words, the advantage of large production in lowering cost increases very slowly after the size of furnace reaches 20 x 80 and the tonnage reaches 300, if the cost of the power for blowing be given due weight.

On the other hand, it will be seen that the cost curve of the 22½-ft. x 90-ft. furnace is much flatter than that of the 20-ft. x 80-ft. and that the most economical point can be exceeded considerably with only a slight increase in cost.

The Effect of Rate of Driving on Profits

It seems likely that cost per ton may at times have received too much consideration and profit per day and per year not enough.

It is very true that during several years out of every ten most furnaces have to figure not how much profit they can make, but how small they can keep their losses, for these cannot be cut short by stopping altogether. Fixed charges of interest, taxes, insurance and some salaries run along just the same, and it pays better to run at a loss that does not exceed this amount than to shut down and break up the organization. But at such times we cannot make all the saving represented by the minimum rate over any higher rate because if we are ever to be able to run at a higher rate the investment in power plant for that rate must have been made and the fixed charges on it will go on just the same.

When we come now to the question of profits the question is not one of minimum cost per ton, but of maximum profit per day. As a general thing a furnace is not built unless its projector can see a profit of \$1.50 as a minimum for a 500-ton furnace costs with its site and all complete nearly \$1,000,000, its output is say, 170,000 tons per year, and \$1.50 per ton profit on this is \$255,000 per year; capital can be scarcely raised for a smaller return than this in so variable a business.

On the basis of the profit consider the case of the 22½-ft. x 90-ft. furnace on the "power value" basis. The minimum cost for these items is at 300 tons and is 0.65, at 500 tons it is 0.76 or \$1.1 cents higher. On this basis the \$255,000 profit per year on 170,000 tons at \$1.50 per ton would become \$1.61 per ton, on three-fifths as much 102,000 tons, or \$164,220 per year, which would naturally be less acceptable to the owner than \$255,000, even though lower costs were made.

It is very obvious from these considerations that 500 tons per day is not the limit of production from the commercial standpoint, and that it is vastly more important to be able to make double the tonnage in good times than it is to make iron for 11 cents less in bad times.

During these relatively rare periods when the profit per ton is several times \$1.50 per ton these considerations become correspondingly more powerful and the furnace must be equipped to make a maximum production during these periods even though the fixed charges during hard times are somewhat harder to carry, because in this way we secure the maximum return over a long period.

By-products

There are two important by-products from the blast furnace, the slag and the surplus gas.

FIG. 2 IRREDUCIBLE LABOR AND BASIC CAPITAL CHARGES PLUS BLOWING POWER REQUIRED AT COST OF PRODUCTION (.25C.) AND AT SELLING VALUE (.50C.) PER HORSEPOWER-HOUR FOR FURNACE OF DIFFERENT SIZES AT DIFFERENT RATES OF PRODUCTION

SLAG

This finds utilization in three ways at the present time in this country; others are used in Europe and are under consideration here. First, as a raw material for cement manufacture; second, as aggregates for concrete; third, as filling material. In Europe it is used to make slag building brick and the heat is used to generate steam.

Blast furnace slag consists principally of the three commonest and least valuable of the components of the earth's crust, silica, alumina and lime; any attempt to utilize it, in order to succeed, must recognize this fact, especially as its composition must be regulated not by the product into which it is to be converted, but principally to suit the conditions of the furnace producing it.

BRICK

The extremely low cost of the natural raw materials for brick manufacture and the high quality of product which can be produced from them has prevented the introduction into the United States of the manufacture on any large scale of slag brick whether cast direct or made by the grinding, mixing and steaming process.

STEAM PRODUCTION FROM SLAG

A plant has been built and operated in England for the production of power from the waste heat of the slag, a project over which many inventors have dreamed.

The development of the low-pressure turbine made the realization of this dream much easier. It seemed only to be necessary to permit the slag to flow into an air-tight chamber containing a good volume of water in the bottom, maintain only enough pressure to exclude the air and utilize the steam formed by the direct action of the slag on the water in a low-pressure turbine.

It was found, however, that the acid vapors generated particularly by the sulphur in the slag ate up the blades of the turbine so rapidly that this plan was out of the question, so a boiler or evaporator was introduced, made of material unaffected by these acids and the original steam was condensed in this with the production of an equivalent amount of pure steam at a somewhat lower pressure. The slag granulated in the first vessel was continuously removed by a bucket elevator working in a sealed compartment.

The success or failure of any such operation depends upon the price of coal in the district and considering the necessarily high plant cost per horsepower of such an installation it seems inherently doubtful whether the value of the equivalent coal saved would pay the high fixed charges. No plant for the generation of power from slag is in use in the United States at this time.

SLAG CEMENT

The slag from a large percentage of the furnaces of the largest iron and steel company in the United States is converted into Portland cement. The slag is granulated by a stream of water as it flows from the furnace, the granulated material is dried, ground, mixed with ground burnt lime in correct proportions, the mixture burnt to clinker in a rotary kiln and the clinker ground to cement. The slag must not contain more than 3 per cent of magnesia in order to make good slag, so the furnaces whose slag is so used are confined to the use of calcite stone. This converts a waste material from a liability to an asset and with the increasing use of concrete the business seems certain to grow, and it is not improbable that better methods of cement manufacture from slag will some day be developed.

SLAG FOR CONCRETE

Slag broken up after being allowed to cool slowly forms excellent aggregates for concrete. Being rough

and irregular it produces an excellent bond with the cement, and unlike limestone it does *not* swell and go to pieces under the effect of fire. Its use for this purpose will grow with wider appreciation of its value.

SLAG FILLING

Slag has been used for reclaiming low land, probably from the earliest days of the blast furnace. In those times it was picked up by hand labor and hauled away cold in carts and wagons, but at present it is either flushed to place with the water used to granulate it or taken to the desired location molten in ladle cars.

When filled to a depth of several feet in the latter way it makes a very solid foundation and is much valued on water-front locations, where cheap transportation has caused the location of so many plants in recent years and where there is usually much low land which can be reclaimed by filling.

When a railroad fill or dam is desired, end dump ladles are very desirable as they build an embankment with almost vertical sides and therefore use a minimum of material to which, however, its practically monolithic structure insures great strength.

THE SURPLUS GAS

In earlier articles we have seen that with good power-plant and stove practice about one-half the gas produced by the furnace is available for other purposes after the furnace requirements have been supplied. As the gas contains about half the heat energy of the coke from which it is produced we evidently have available in such a case about 25 per cent of the energy of the coke. This means in the case of a fairly economical 500-ton furnace the heat equivalent of about 100 tons of coal per day. This is evidently an asset of no mean size even where fuel is cheap. How shall we utilize it?

The answer to this question is indissolubly bound up with that of the type of blowing engine to be adopted, already discussed in the article on blowing machinery.

When the furnace is operated in connection with steel works, as about 75 per cent of the furnace capacity is, the steel mill being a heavy consumer of power, the proper and obvious procedure is to convert the heat into power and use it in the steel mill, as is the universal practice in such cases.

The question of the best method to be followed is, however, by no means definitely settled. For those engines in the mill which are steam-driven there is, of course, only one solution, to use the gas for the production of steam, but the power used in mills is increasingly electricity and the question of how best to generate this power is a matter for discussion. The general considerations governing the matter are shown by the following quotations from a lecture before the students of Pennsylvania State College, March, 1915.

The gas engine works on a totally different principle from either the steam engine or the steam turbine and has consequently very different characteristics. It is not capable of much change in speed and its economy drops very rapidly as the load falls off, largely because the friction of the engine is very high and almost constant irrespective of the load, so that a friction of 20 per cent at full load means one of 40 per cent at half load, and so on.

This type of engine is also capable of carrying only very slight overloads, that is to say, its most economical load is its maximum load, and any overload capacity is secured only at the expense of economy and at the price of buying a larger engine. In these respects it is at a great disadvantage as compared with either the steam engine or the turbine, both of which have a large overload capacity which extends far beyond their most economical load.

On the other hand, the gas engine cuts out entirely the boiler, and above all, it has a heat consumption only about two-thirds or three-fourths of that of the best steam plants.

It was at one time supposed that this fact was destined to make the gas engine the preferred prime mover for all electric power work, but other considerations came in and this expectation has not been realized; and some of the best gas-engine men admit that where coal is the fuel used its day of realization has been indefinitely deferred.

Leaving out of consideration altogether the question of first cost and capital charges for the present, let us consider only the operation. Before coal can be used for gas engines, it must be gasified in a gas producer—an apparatus having an efficiency when delivering cold gas (which a gas engine must have) of 75 to 80 per cent, which is almost the same as that of a well-designed and operated boiler plant. So on that basis the two are even. But while coal may be burnt under boilers for a few cents a ton, say 15 cents, in large plants, it cannot be gasified for much less than 45 cents and often 50 cents.

Now the efficiencies of the producer and the boiler being almost the same, the fuel consumed will be in the same ratio as the heat consumption of the two motors themselves, say as a liberal figure 14,000 B.t.u. for the turbine, and 12,300 for the gas engine, a ratio of 1.17 to 1. Then if the coal cost is \$1.00 delivered, its cost burned under boilers is \$1.15 and gasified \$1.45. The fuel cost is proportional, therefore it is $\$1.15 \times 1.17 = \1.34 for the steam turbine and \$1.45 for the gas engine. That is, the heat units used by the gas engine are less, but the money cost of fuel is more.

This is all based on full-load conditions, and while the cost for both goes up very rapidly for light loads, owing to the far flatter heat-consumption curve of the turbine and its smaller relative size due to its much greater over-load capacity, its heat consumption rises much more slowly and as the use factor in public service work is about 30 to 40 per cent, it will be perfectly obvious that the advantage of the turbine over the gas engine will be much greater on the average than it is at maximum load, even on the heat-unit basis. Of course, as the cost of coal rises, the case becomes more favorable for the gas engine, at full load, but it is very doubtful if under any ordinary commercial conditions its practical economy on the average is much higher than that of the turbine.

When we come to the iron industry we come to a different condition, very much more favorable to the gas engine. This is that the fuel to be used is already gasified by the blast furnace, this gas being in fact almost an ideal fuel for gas engines, and they are, therefore, entirely freed from any charge or loss of heat for gasification, except that the sensible heat of the gas, 6-8 per cent in good practice, must be sacrificed to fit it for gas-engine use.

The steam plant, on the other hand, is under the necessity of burning this gas under boilers with the same losses as occur in coal firing, excepting that the labor cost is very small. In the past, the economy of furnace boilers has been extremely poor. I have tested boilers on which it was down to 30 per cent. Fifty per cent was about average practice until quite recently, but just at the present time this subject is receiving great attention and boilers are being operated at an efficiency of 75 to 80 per cent in regular operation. In this case the full-load fuel consumptions are proportional to $0.77/1.17 = 0.66$ and $(1.00-0.07) = 0.93$, or 1.41 to 1, with the further advantage that the gas engine is enabled to dispense with one whole operation and

its attendant bother, the gasification of the coal. Moreover, the gas engine has in this service a further great advantage. The use factor is about 60 per cent for electric service in the steel industry, while for blowing engines it is near 80 per cent. Why then are these engines not in universal use in such plants? Here we come to the real milk of the cocoanut.

We have hitherto said nothing of comparative labor costs and of capital charges. In regard to the former the gas engine has had a bad name. The stresses which it undergoes are tremendous, and breakdowns in the past were frequent and serious, while the uncertainty of the engine's going at all was a decided factor in its early days. But if you remember the prayerful uncertainty with which a man started out on an automobile trip ten or twelve years ago, not knowing when or how he would return, and consider our present entire disregard of this as an important factor, you will admit that many of the defects of that type of motor have been removed and that its reliability now fairly challenges that of the steam engine, a condition which is rapidly becoming, if it has not already become, true of the larger types which we are considering. Nevertheless, the number of parts and variety of their movements is vastly greater in this engine than in the turbine and the cost of supervision and operation is correspondingly greater; but leaving this question for a few minutes let us turn to that of capital charges.

These are made up of straight interest and an additional percentage on the investment which is set aside and saved at compound interest, so that at the end of the reasonable life of the plant we may have a sum in the bank equal to the original investment with which we can either pay off the investor or buy a new plant. Any operation which figures its costs on any other basis will probably go broke and certainly ought to. Five per cent at compound interest will equal the principal in about fourteen years, which is about all the life we have a right to expect from a power plant, for if it is not worn out in that time it has most likely been designed off the map. In other words, later improvements will have then made it commercially undesirable to operate any longer, even though it be not nearly worn out.

This 5 per cent added to the 7 per cent interest rate, which must be figured on industrial plants, gives us 12 per cent capital charges over and above all operating costs of every kind. This is a minimum figure for plants of this kind. Make no mistake; these are not bookkeeping figures, and the shores of commercial history are covered with the wrecks of plants which failed to provide for these charges. No sensible business man will put money into a property which cannot figure on this basis and still show a profit.

We see, then, that the annual cost of power is made up of fuel, labor, and one-eighth of the cost of the plant. Let me illustrate this to you. I know of a plant where a furnace is blown with two gas-blowing engines which cost about \$100,000 apiece, and which with foundation, house, crane and gas-cleaning apparatus and connections erected complete did not cost less than \$275,000. They develop together about 2500 hp., or a cost of \$110 per horsepower installed. Coal of 14,000 B.t.u. in this region costs about \$1 at the plant.

Steam engines of the best type, with their boilers and all accessories complete could have been installed for \$55 per horsepower. These engines would have been required certainly not to exceed 18,000 B.t.u. per horsepower-hour delivered to the boiler, while the gas engine may get along on 12,000. Counting 8780 hours per year, the loss of thermal units per year is $6000 \times$

8780 = 52,600,000 B.t.u. That is a large number of heat units. But how much money does it represent? One ton of coal costs fired say \$1.15 and contains $2240 \times 14,000 = 31,000,000$ B.t.u. In other words, it would require $1 \frac{2}{3}$ tons of coal per horsepower a year to make up the steam plant's deficiencies, or say, \$2 worth.

The difference in fixed charges, on the other hand, is 12 per cent of $(110-55) = \$6.60$ or a net loss of \$4.60 per horsepower year by the use of the gas engine with 100 per cent use factor. On the other hand, gas blowing engines are now being built which can be installed for \$75 per horsepower, and if these were used in a region where coal cost \$2.50 per ton, the cost of make-up coal would be \$4.20 and the fixed charges on increased investment be $0.12 \times (75-55) = \$2.40$, a difference of \$1.80 in favor of the gas engine under these conditions. This is a little less than 10 per cent on the additional capital required for the gas engine and might be considered a paying though by no means a startling investment, because owing to the uncertainties of industrial earnings, investors are not commonly interested in them unless they can see a manufacturing profit of about 15 per cent; and it is obvious that any additional expenditure required should show this amount or over to be justified. In this case the amount is 7 per cent interest plus 9 per cent net saving or 16 per cent in all. It is right in this range of conditions that it begins to be good business to install gas-blowing engines, though some authorities would insist that at least 2 to 3 per cent larger capital charges should be assessed against the gas engine on account of its high rate of physical depreciation, and all the evidence I have indicates that this is correct.

Turning now to the generation of electric power, we find the conditions different again because we have on the steam side the turbine with the direct rotary movement and its great capacity, while on the other we have the relatively slow speed of the gas engine and the consequent high cost of its generator with probably greater friction and less efficiency than when connected to a blower.

For these conditions we may take costs of \$70 and \$50 respectively per kilowatt installed and heat consumptions respectively of $12,500 \div 94 = 13,300$ B.t.u. per horsepower for the gas engine, and $12,500 \times 0.96$

$\frac{12,500 \times 0.96}{0.77} = 15,600$ per horsepower for the turbine, or 17,700 and 21,750 per kilowatt-hour respectively.

The use factor is much lower in electric service than it is in blowing-engine service. If we take 60 per cent we shall be liberal. This means that on account of peak loads for which it is necessary to provide, the plant in the course of a year will only put out 60 per cent of its maximum rated power. This factor varies very much in different works, but is higher in all of them than in public service plants.

The heat consumptions are about what may be expected under such conditions of loading and are not altered by this condition and neither are the costs, but the relative relations of these two are profoundly altered.

The excess thermal units per kilowatt year at full-rated capacity for the turbine above those for the gas engine are $8780 \times (21,750 - 17,300) = 39,100,000$, and the coal to supply this at 31,000,000 B.t.u. per ton is 1.26 tons at \$2.50 per ton. This is worth \$3.15, but the use factor is only 60 per cent, so that only 60 per cent as much coal is required for make-up, and its value drops to \$1.90 while the fixed charges are $12 (70 - 50) = \$2.40$.

In other words, in such a case the saving in coal

would not pay all the capital charges in the increased investment which therefore would be a bad one. Moreover, while the cost of labor and supervision for gas blowers may be no greater than that for steam engines and boilers together, undoubtedly their cost for gas-driven generators is greater than it is for steam turbines and boilers, and this increased cost would further throw the scale against the gas engine. But as the cost of coal rises, conditions are reached under which the gas engine pays, while as its first cost falls the fixed charges fall also, and tend to make its employment sound from the business point of view.

It will now be seen, I think why John Doe in Tyrone, where coal is cheap, may be a fool to do what had paid Richard Roe well in Boston where coal is dear, and the engine that is the most economical of coal may be a lot the most wasteful of dollars.

There are certain electrical considerations involved in the very variable load of the steel mill that give the turbo-generator advantages not covered by this discussion, but of great importance and very tangible value in operation. These considerations probably make it desirable, if not essential, that part of the electric power at least be developed by turbo-generators even if the main supply be from gas engines.

One fact cannot be too strongly emphasized. This is that the decision that a certain type of mover is the best for blowing purposes by no means involves the conclusion that the same type is best for electric power developments. One principal reason for this is that the blowing power for each furnace necessarily being isolated, the largest blowing unit is limited at the most to about 2500 hp., that being the approximate power required to blow a 500-ton furnace, and for safety it is desirable to have this divided into two units, whereas electric units may be built as large as 35,000 hp., and these larger ones are lower in both first and operating cost than the smaller ones, while they are entirely free from the electrical troubles due to variation in angular velocity to which the gas engine is liable.

The greater reliability and smaller upkeep of the turbine give it an advantage over the gas engine not fully covered even by the necessary allowance in operating costs, because certainty of operation has a cash value from the point of view of the whole works which power cost does not touch.

For the generation of electric power the reciprocating steam engine on account of high first cost of generator and higher operating cost is not to be compared with the turbine in powers larger than 2000 hp.

One factor of great importance in decision as between gas and steam engines is that of the efficiency with which the gas is burned under the boilers, while the efficiency of combustion in stoves has an enormous effect on the quantity of gas used for that purpose or left for outside utilization. For many years gas was burnt most wastefully as no attention was paid to the subject, but in recent years it has been carefully investigated and vastly improved. Diehl, Eldridge, Bradford, Boynton, Green, Huessner and a host of others have investigated existing burners and built better ones until the efficiency of boilers using furnace gas has gone from about 50 per cent to over 70 per cent in many cases and nearly 80 per cent in some. With this has gone an increase in the steam produced per boiler which, of course, cuts down the capital cost as well as the fuel cost.

The result is that while the steam motor might have been at a hopeless disadvantage even in spite of its advantage in fixed and operating costs a few years ago, it might easily beat the gas engine on the same basis to-day. The general principles on which these improvements have been made are simple, being merely the

well-known principles of all good combustion, first, correct proportioning of gas and air on the injector principle so that a change in the rate of flow of one makes a corresponding change in the flow of the other; second, the thorough mixing of the air and gas before they reach the zone of combustion; third, the control of the draft at the outlet to the stack so as to maintain the rate of flow of the products of combustion at the best velocity without drawing in any excess air.

The establishment of these conditions may require that either the air or gas be put under light pressure by a fan to supply the velocity required for injector action and for proper mixing, also in some cases to give sufficient velocity without excessive stack draft. The expense of operating the fan is insignificant in comparison with the enormous saving made by the improvement in combustion when these principles are correctly applied.

Where a furnace is not operated in conjunction with steel works there may still be a market for the surplus gas. This may be developed in the form of a sale of electric power to the public service company, but the stringent requirements of continuity in that service have made many operators chary of contracting with them.

Where the gas cannot be sold in this way it may be sold for heating purposes, but the field is rather limited, because the small heat value of the gas makes its transportation expensive and unfits it for any but relatively low temperature operations since the combustion temperature of furnace gas is not high.

In spite of these difficulties the enormous potential value of the gas justifies far greater efforts to conserve and sell its energy than have been made in the past.

In conclusion it is worth repeating that the possibility of disposing of this asset either as electric energy or heat is much greater in the vicinity of a city, and this is destined to induce the location of merchant furnace plants near thickly settled communities in the future to a greater extent than in the past.

Commercial Limitations to Fuel Economy

A few years ago the maximum degree of fuel economy was not only technically desirable, but was commercially necessary for survival, but this is no longer the case. There are conditions in which the commercial results are better with very moderate fuel economy than with the highest. The two developments which have brought about this change are the introduction of the by-product oven and the economic development of power generation with furnace gas, especially the gas engine.

One of the fundamental conditions for the occurrence of this paradox is that there shall be a market for all the surplus power developed. Let us assume then, the most common case of a combined plant of blast furnaces and steel works in which the latter furnish a market for all the power which can be supplied by the former. Assuming a high cost of coal brings out the facts more clearly, let us then assume that coking coal costs \$2.10 delivered at the works. If this were coked in old-fashioned ovens the yield would be about 60 per cent and the coking cost would be about 60 cents per ton of coke; coke, therefore, would cost $2.10 \div 0.6 + 0.60 = \$4.10$ per ton, and this cost would represent less than 60 per cent of the heat value of the fuel. The same coke in modern by-product ovens would yield 70 per cent of good screened coke, and the coking cost would be about 75 cents per ton of coke, so that coke would

cost $\frac{2.10}{0.7} + 0.75 = \3.75 per ton. There are, however,

some important deductions from this figure. The gas can be sold to the steel works for heating furnaces, the tar and ammonia are recovered (the latter in the form of ammonium sulphate) and sold; while under present and probably future conditions the benzol can be recovered at a handsome profit also.

The value of these by-products varies with the location, but is seldom or never less than \$1 per ton of coal. In a region of high-priced fuel such as we have assumed, \$1.50 per ton of coke would be a safe estimate. This would reduce the cost of coke to \$2.25 per ton; in other words under such circumstances a ton of coke would cost little more than a ton of coal in spite of the loss of weight and the cost of the operation.

Cases exist in which the coke actually costs less per ton than the coal from which it is made, the value of the by-products making up all the losses and paying all the costs of the operation.

Turning now to the utilization of the coke, all the heat energy it contains, not consumed in the necessary operations of the blast furnace, is returned in the form of gas, and because this gas contains only a small percentage of its heat in sensible form the efficiency of conversion is very high. Ordinarily the sensible heat of the gas is less than 5 per cent of the heat of the coke, and we may say that the efficiency of the blast furnace in its double function of iron maker and gas producer is 95 per cent; or, on a more conservative basis, we can say that since only about 10 per cent of the total energy of the gas is sensible heat the efficiency of the blast furnace as a gas producer alone is 90 per cent or better, whereas that of the standard gas producer, measured on the basis of the energy in the cold gas divided by that in the coal, is only about 65 to 75 per cent.

We have already seen that the gas engine has a considerable advantage over the steam turbine in heat consumption, if we start with gaseous fuel; and the tremendous efficiency of the blast furnace as a gas producer enables us to utilize this advantage of the gas engine in regions of high-priced fuel where the saving will pay the fixed charges on the greater investment.

In other words, admitting as we must, that there are considerable technical advantages in the use of gaseous fuel for power development, it is obvious that these may be commercially realized much more easily when the gasification is done as it is in the blast furnace with a thermal efficiency of 90 per cent and without labor and capital charges than they can when the efficiency of gasification is 65 per cent and the cost 50 cents per ton of fuel, as in the gas producer.

If we convert as much of the coal into coke as the furnace can conveniently take and utilize the resulting gas to the full, the total fuel and power bill measured in dollars and including fixed charges of a combined plant under such conditions is smaller than if we work with the highest fuel economy in the furnace and supplement the power required by the use of coal either in gas producers or under boilers. Of course, the ability of the furnace to consume coke is limited and its output of iron increases, other things being equal, as the coke per ton of iron decreases, and if we tried to run the coke per ton of iron unreasonably high the iron output would fall and profits be seriously reduced.

It is worthy of note that the highest fuel economy can only be obtained with very high blast heats, which means a decided increase in the gas required for blast heating. After we have reached the limit of commercial coke economy every such increase in gas consumption for this purpose represents an absolute loss.

It is worthy of note also that these conditions bring about a justification for high solution loss, since we

have seen that solution cools down the top gases and reduces the loss due to sensible heat, and it reduces the quantity of blast required per pound of coke and thereby reduces the pressure required to blow the furnace so that there is a material saving in the power consumed per ton of iron, for blowing.

It cannot, however, be too strongly emphasized that where these conditions do not prevail, where the cost per thermal unit of coke is materially higher than that of coal, or where there is no market for all the power which can be produced, or the cost of coal is too low to justify the completest utilization of gas, fuel economy is just as important as it ever was. These are the conditions which generally prevail at merchant furnaces, especially those which buy their coke.

The Dry Blast

The fact that the large steel works of the country have generally not installed dry blast plants has led some of those interested in such matters to believe that there was no ground for the claims of fuel economy made for dry blast, but nothing could be further from the facts. The real case of the dry blast depends upon the considerations set forth in the last section. Where it does not pay commercially to run the furnace for maximum economy for reasons there set forth, obviously it may not pay to install dry blast to obtain fuel economy; but, on the other hand, in the many cases where every pound of coke burnt unnecessarily means so much money lost, especially where the climate is damp, the dry blast is commonly a highly profitable investment.

There are special conditions in which furnaces have available more blast heat than they need or can use, and in such cases the only gain from the dry blast is the increased uniformity of operation, and it is a matter for careful consideration whether dry blast will pay or not.

The most marked instance of this kind is the charcoal furnace with high-blast heat and on rich ores. In the case cited in the article on thermal principles the "hooding in" of the air cylinder of the blowing engine resulted in lowering the moisture very decidedly, but did not have any effect on the fuel economy, and the application of the dry blast to another charcoal furnace running under similar conditions did not have any adequate result on the fuel consumption.

On the other hand, practically all the tests made at merchant coke furnaces equipped with dry-blast plants have shown a saving in coke and an increase in product of a value to pay for the dry-blast plant in two or three years.

It is very unfortunate that dry-blast plants have hitherto not been built in the South where the humidity is high, with the exception of one plant which has not been operated long enough at this writing to demonstrate the advantages of the process in that region. But I have taken records for years at a time which showed a fuel consumption lower by 20 per cent in the dry than in the humid season, and this represented only a part of the total saving. For during the humid season the margin of hearth heat was reduced to the point where slight variations were liable to throw the furnace completely off its balance, and the hearth heat per pound of fuel being very small the furnace was not sensitive to changes of burden and, therefore, very difficult to keep in regular operation. Serious troubles such as breakouts were very much more common, and as a result the operating costs were very much higher during the humid season.

This was so serious that as long ago as 1896 I endeavored to induce the owners to install refrigerating

apparatus to dry the blast, and was able to show to my own complete satisfaction that it would have been a vastly profitable investment, but no attention was paid to the suggestion by the owners. This was eight years before the publication of Mr. Gayley's results, and none of us had the slightest idea that anyone else was working on the plan, though I subsequently found that Mr. Gayley had taken out patents on the process two years before I started on it.

On another occasion in the Birmingham district, furnaces running on foundry iron fell off in the grades produced in the early spring, a time when ordinarily the humidity is quite low, but the season had been a very warm one, and when I consulted the humidity records I was astonished to find that the humidity had risen enough to account for the increased coke required to restore the grades, a very considerable amount.

Two points in connection with dry blast are of much importance; first, it is the absolute and not the relative humidity on which the possible saving depends; second, the amount of saving possible is susceptible of reasonably accurate calculations. The relative humidity means the percentage of the moisture which the air actually contains measured in terms of the amount it would contain if saturated at *that temperature*. But the amount of moisture which the air contains at saturation increases with great rapidity as the temperature rises.

Referring to the chart given in the chapter on dry blast, it will be seen that at 0 deg. Fahr. this amount is 0.05 lb. per thousand cubic feet; at 32 deg. Fahr., 0.27 lb.; at 60 deg. Fahr., 0.8 lb.; at 70 deg. Fahr., 1.13 lb., and at 80 deg. Fahr., 1.6 lb; therefore the humidity in percentage means nothing whatever unless we know the temperature. On a foggy day with the temperature at 32 the humidity seems excessive, and in fact fog means that the air is super-saturated; while on a summer day with the thermometer at 80 and the humidity 50 per cent of saturation the air would seem excessively dry, but in the latter case it would contain nearly three times as much moisture per cubic foot as in the former.

We can determine the fuel saving possible in any given case where the humidity during each month of the year is known by the use of the charts of hearth heat in the article on thermal principles. We first determine the average absolute moisture in the air for each month, then decide on the point to which it will pay to dry it, and deduct the coke consumption for the second case from that of the first. To do this, of course, requires a knowledge of the blast and critical temperatures, at least approximately, for the given conditions.

The humidity in the air for each month can be obtained from the nearest Weather Bureau Station. It is desirable to obtain it for at least two years and average the results. This information (furnished freely by the Weather Bureau officials) forms an excellent basis on which to start, but it is necessary to have in mind that these stations are generally located at the highest point available and that the humidity at the ground level may be locally very much higher, especially on the banks of large bodies of water, rivers, lakes or cooling ponds, where furnaces are usually located. Cooling ponds and rivers in industrial districts in particular are likely to throw off large volumes of moisture, even beyond the saturation point of the surrounding air. Within a few hundred yards this is all absorbed and averaged up in the vast volumes of surrounding dry air, so the results at the Weather Station may not be much affected, but the local increase in humidity in the vicinity of the plant may be commercially of great importance.

For the reason it is well to determine definitely the humidity in the vicinity of the blowing engine intake over a period of several weeks at least, and compare the results with those of the Weather Bureau. A few weeks will generally give a fair idea of the local increase, but of course it is desirable to have it for a year if possible.

Knowing the coke saving per ton, and the cost of coke, and the tonnage made per day, we can easily figure the saving from this source. A comparison of this with the cost of a dry-blast plant will generally show that at merchant furnaces without a market for their surplus power the saving will pay for the installation in a short time.

In addition to the saving in fuel and the corresponding increase in tonnage which results, there is a saving in smoothing out the irregularities which result from variations in humidity, whose effect as explained above may be very serious from a financial point of view. This saving, due to the uniformity, has sometimes been claimed to be greater than that due to the drying itself, and while I cannot subscribe to that view there is no doubt that it is extremely important, especially in the case of merchant furnaces where the control of grades is so much more important commercially than at steel works' furnaces.

We can then summarize the status of the dry blast as follows: If first there is a market for heat in the form of combustible gas at a price per thermal unit equal to or better than that for coal, and second, if the money cost of a thermal unit in the form of coke is but little greater than that in the form of coal, the fuel economy in the furnace beyond a point soon reached has a negative value and a dry-blast plant to promote fuel economy, accordingly cannot ordinarily pay. Or where the furnace has available from hot blast alone more hearth heat than it needs for its conditions (practically, this means only charcoal practice on rich ores), the advantage of the dry blast becomes a very secondary one. But where coke consumption reduced means money saved, and where strict grade control means more money earned, then the dry-blast plant is usually a highly profitable investment.

In conclusion it may be pointed out that the introduction of the by-product oven by reducing the value of coke in comparison to that of the coal from which it is made, and the gas engine by giving to the surplus gas from the furnace a commercial value per thermal unit, in some cases equal to that of the coke itself, have been the principal causes of the non-introduction of dry-blast plants at steel works' furnaces.

Annealing of Aluminium*

BY RICHARD SELIGMAN AND PERCY WILLIAMS

It has been shown by various workers that hard worked amorphous metals undergo changes at comparatively low temperatures. Thus Beilby¹ points out that a rapid release of strain occurs in hard worked metals at 100 deg. C., while Lowry and Parker², when studying the specific gravity of aluminium filings, observed a decrease in the gravity when the filings were heated to 100 deg. C. Recently Brislee has observed changes in various physical properties of aluminium at 100 deg. C.³

During the course of a long series of experiments upon the solubility of aluminium in nitric acid it has been noticed incidentally that by heating hard worked metal to 125 deg. C. a definite change in the rate of dis-

solution is brought about. Hard worked aluminium is more readily soluble in nitric acid than the same metal when annealed. Thus, for instance, a sample of hard worked aluminium which lost 56 mgr. per 100 sq. cm. per twenty-four hours when immersed in 1.42 nitric only lost 39 mgr. when similarly exposed after being annealed at 500 deg. C., a decrease of 30 per cent.

When the hard worked sheet was heated for 10 hours at 125 deg. C., it was found that the rate of dissolution had fallen from 56 to 53 mgr. per 100 sq. cm. per twenty-four hours. This is equivalent to a decrease of 5.3 per cent. Strips heated at 100 deg. C. instead of 125 deg. C. gave similar results, although the reduction of the rate of dissolution was somewhat smaller, namely, about 3 per cent.

It was anticipated that if the heating were prolonged the decrease in the rate of dissolution might be augmented. This was not found to be the case, but, on the contrary, as the heating at 125 deg. C. was prolonged the fall in the rate of dissolution diminished, until samples heated for 80 hours at 125 deg. C. showed the same or even a slightly higher rate of dissolution than samples which had not been heated at all. This reversal was not noted in the case of samples heated at 100 deg. C., but was observed in a large number of samples heated at 125 deg. C.

The facts recited do not appear to tally completely with the observations of other workers. A release of strain as indicated by Beilby should be accompanied by a reduction in the rate of dissolution, but such a release of strain would not account for the subsequent increase. An allotropic change such as Cohen and others describe for many metals would fit in with the changes in the rate of dissolution observed but for the fact that the reversal took place at the temperature which had brought about the first change. Finally, Brislee appears to differ from all others in that the change he observed went much farther, and seemed to indicate progressive crystallization even at 100 deg. C.

A further anomaly has been observed in dealing with metal annealed at higher temperatures. It has been noted on many occasions that aluminium which has been freshly annealed has a lower rate of dissolution in nitric acid than a sample of the same metal which has been allowed to stand for several days after annealing. Thus, for instance, a sample of metal which, when freshly annealed at 440 deg. C., dissolved in nitric acid at the rate of 31 mgr. per 100 sq. cm. per twenty-four hours, dissolved at the rate of 36 mgr. thirteen days after annealing. On re-annealing at 440 deg. C., the rate of dissolution fell again to 32 mgr. per 100 sq. cm. per twenty-four hours.

Attention is drawn to these facts in the hope that it may be possible for some of those who are interested in these changes to investigate them more closely, as the present authors are not likely to have an opportunity of pursuing the matter farther.

Glass-Enameled Steel Apparatus.—The Pfaunder Co., Rochester, N. Y., has issued chemical trades bulletin C-3, describing Pfaunder glass-enameled steel apparatus for chemical industries.

The General Electric Co., Schenectady, N. Y., is planning an interesting exhibit at the Foundry and Machine Exhibition to be held at The Wigmore Coliseum, Cleveland, Ohio, during the week of September 11, in conjunction with the Convention of the American Institute of Metals and the American Foundrymen's Association. The exhibit will include an interesting line of control devices, switchboards, panels, and other material, with a 300-ampere portable arc-welding outfit.

The Time Factor in the Formation of Aromatic Hydrocarbons from a Paraffin Base Oil

BY GUSTAV EGLOFF AND THOMAS J. TWOMEY

The time factor in the thermal decomposition of hydrocarbon oils for the formation of oil gas, gasoline or aromatic compounds of the benzene series is quite as important as the other four variables of chemical reactions: temperature, pressure, concentration and catalysis. In this communication the time factor has been studied in the formation of aromatic hydrocarbons from a paraffin base oil at constant temperature and pressure.

The time factor has been noted by a number of investigators in the thermolizing of a gas oil, for the production of oil gas. Hempel¹ has followed the effect of time upon the composition of oil gas from the cracking of gas oils at temperatures between 700 deg. and 900 deg. C. Tocher² and Jones³ have reported results as to the effect of time upon the products from the heat treatment of oils.

The most systematic piece of work upon the time factor in relationship to the decomposition of a kerosene oil and the resulting products in the gas formed has been made by Whitaker and Alexander.⁴ They have shown that the control of the gaseous products formed from the decomposition of a hydrocarbon oil is a function of the time factor when cracking takes place at constant temperature and pressure.

Rittman⁵ and co-workers in thermolizing an Oklahoma crude petroleum oil for the production of benzene and toluene at constant temperature, pressure and rates of oil flow from 11 to 27 gal. per hour, found that as the oil rate increased decrease of decomposition of the starting oil occurred. No marked percentage change in the starting oil took place as the rate was increased. A change of only 8 per cent is recorded. This was explained upon the basis of insufficient condensation of the system. Nevertheless, the data as expressed in Table 2 are good qualitative information as to the effect of time upon aromatic formation from a petroleum crude oil. Table 1 gives the analysis of the starting oil, using a Hempel distillation set⁶

statement the total progress of a chemical reaction which occurs in a homogeneous system is determined by the difference of the two reaction velocities of the system going in opposite directions as expressed by a reaction equation. From this the velocity of a reaction at every instant of time, *i. e.* the amount of material changed per unit time, may be expressed in the following manner:

The representation of any chemical equation may be expressed:

This reciprocal reaction, each of which has a separate reaction velocity and, expressed symbolically, gives:

$$v = k(A_1)^{n_1}(A_2)^{n_2} \dots \quad v' = k'(A'_1)^{n'_1}(A'_2)^{n'_2} \dots$$

The change per increment of time $\frac{dx}{dt}$ is shown as follows:

$$\frac{dx}{dt} = v - v' = k(A_1)^{n_1}(A_2)^{n_2} \dots - k'(A'_1)^{n'_1}(A'_2)^{n'_2} \dots$$

k and k' are speed constants of the two opposing reactions, $A_1, A_2, \dots$ are the concentrations of the reacting substances, $n_1, n_2, \dots$ are the coefficients of the reacting substances derived from a balanced reaction equation.

Though the above relationships have been studied for reactions of uni, di, tri and higher molecular reactions in which the time factor has been followed, no such relatively simple conditions in a thermolized oil sub-

jected to varying rates of oil flow exists. The cracked oil is an enormously complex mixture of aliphatic and aromatic hydrocarbons and at present the quantitative application of the mass action law is of small value in a study of the temperature, pressure, and time factor involved in the cracking of hydrocarbon oils for aromatic formation.

In this study the effect of rate of oil flow upon the products produced from the reaction at constant temperature and pressure has been made. When the oil is passed into the cracking area, at rates from 12 to 36 gal. per hour, the rates may be expressed in the time factor units as given in Table 3.

The experimental values from Table 5, of 12 gal. per hour, which in point of time gives 5 minutes per gallon of oil in the vapor state, gave maximum decomposition of the starting oil. As the time decreases in which 1 gal. of vaporized oil is in the heated area of the tube, the amount of initial oil decreases. Now in chemical reactions, the time factor which is representative of the interval of time during which a reaction progresses, as illustrated by the above equations, is theoretically deducible from reaction velocity considerations. As shown from the data, increase of rate of oil flow decreases the time in which the oil vapors are in the reaction zone of the heated tube.

Analysis of the Oil Used

The paraffin base oil utilized in these experiments was one which is commonly called a distillate or gas oil. It was derived from a paraffin base Pennsylvania crude petroleum and analyzed as follows: It boiled between the ranges of 200 deg. and 350 deg. C. to the extent of 95.3 per cent. Distillation of the oil was de-

Twenty gallons of oil were used in each experiment.

Experimental Procedure

The paraffin base oil was pumped through a carefully calibrated oil meter at rates from 12 to 36 gal. per hour, at constant temperature of 700 deg. C. and pressure of 150 lb. per sq. in.

The system which was a closed one consisted es-

FIG. 1—THE EFFECT OF RATE OF OIL FLOW ON THE PER CENT OF RECOVERED OIL—AND THE SPECIFIC GRAVITY OF THE RECOVERED OIL

sentially of a lap welded steel tube of $\frac{5}{8}$ in. wall, 11½ ft. in length and 8 in. in diameter. The steel tube was connected with a tar body and stirring rod device for the removal of any carbon formed upon the inner wall of the tube. From the fan box above the tar body a 3-in. header ran to the condensing system which was adequate for these experiments. A triplex pump with an accumulator for the pumping of the oil against the 150-lb. of gas pressure of the system was efficient. A gas-heated muffle-type furnace was used.

Before each run the pressure was built up by means of a compressor to 150 lb. with natural gas. The temperature control was determined by means of a base metal thermo-couple which was accurate to 5 deg. C. plus or minus.

The rate of oil flow into the cracking area under constant temperature and pressure was: 12, 16, 23, 30 and 36 gal. per hour. Before each run the oil meter was carefully calibrated, due to difficulty in finding an oil meter which would remain accurate for any length of time.

By careful regulation of the pressure in the cracking system, the rate of oil flow was maintained constant by the pump. The excess pressure built up by the cracking of the oil was released by means of a pressure valve

and was never allowed to exceed or fall below 150 lb. pressure; for change in pressure exerts a marked influence upon the decomposition of the starting oil. The temperature, pressure and rate of oil flow during each experiment were held constant.

Experimental Data

The data as experimentally determined are brought out by means of the following tables and figures:

Table 5 and Fig. 1 give the effect of rate of oil flow on the per cent. of recovered oil and the specific gravity of the recovered oil.

Table 6 and Fig. 2 give the effect of rate of oil flow on the formation of benzene, toluene and xylene in the recovered oil.

Discussion of Experimental Data

A.—THE EFFECT OF RATE OF OIL FLOW ON THE PER CENT OF RECOVERED OIL AND THE SPECIFIC GRAVITY OF THE RECOVERED OIL

When a paraffin base oil is passed through a heated tube above the vaporization point of the hydrocarbons present, dependent upon the temperature of decomposition profound changes take place in the starting oil.

The oil recovered from the cracking is composed of aliphatic and aromatic hydrocarbons differing in their constitution as the temperature is increased.

Likewise the time factor or the rate of oil flow into the heated area of the tube brings about profound changes in the initial oil. By varying the time factor at constant temperature and pressure, the recovered oil differed in constitution from the starting oil and from each other widely.

From Fig. 1 it will be observed that the rate of oil flow has a marked effect upon the per cent of recovered oil obtained in each experiment.

A priori reasoning would indicate that the amount of decomposition of the oil should be directly proportional to the time factor or rate of oil flow. Quite different results were obtained experimentally.

The maximum decomposition took place between 12 and 16 gal. per hour, where for each gallon change in rate a difference of 3.05 per cent in the recovered oil resulted. From 16 to 23 gal. per hour a change of 2.16 per cent took place per gallon change in rate. The minimum of change took place between the rates 23 and 30 of 1.2 per cent. As the rate was increased from 30 to 36 the change per gallon of oil flow gave a 2.05 per cent difference in the recovered oil.

This indicates the close inter-relationship of the temperature and the time factor, for in a previous set of experiments where the temperature effect was studied, a critical temperature drop was noted quite similar in its characteristics, to the time factor.¹ The per cent of recovered oil increased as the rate of oil flow was in-

creased, while the per cent of recovered oil decreased with increase of temperature.

The specific gravity changed from 0.827 in the initial oil to 0.978 in the recovered oil as the rate of oil flow decreased from 36 to 12 gal. per hour.

With increase of temperature the specific gravity of the recovered oil increased also. This is in accord with the increase of specific gravity with increase of the time factor.

Due to the time factor at constant temperature of 700 deg. C. and 150 lb. pressure, the initial oil had changed from a paraffin oil to a mixture of paraffin, ethylene and perhaps acetylene series, and, aromatic hydrocarbons of the benzene and polycyclic series hydrocarbons.

From the high specific gravity of 0.978 in the 12 gal. per hour experiment, the lowest oil flow, the maximum aromatic formation is indicated.²

B.—THE EFFECT OF RATE OF OIL FLOW ON THE FORMATION OF BENZENE, TOLUENE AND XYLENE IN THE RECOVERED OIL

The effect of rate of oil flow upon the formation of benzene, toluene and xylene in the recovered oil is brought out by the data and Fig. 2. The interesting fact to be noted in the graph is that as the initial oil in the vapor state is allowed to remain in the heated zone the least in point of time or the maximum rate of 36 gal. per hour, the toluene and xylene form in greater quantity than benzene. This is equivalent to cracking at low temperature.³

As the time factor is increased benzene forms more rapidly than either toluene or xylene and at the maximum time of 5 minutes per gallon of vaporized oil in the heated zone, benzene formed is over twice the per cent of toluene and over seven times that of xylene.

The per cent of benzene decreased with increase of rate of oil flow from 12 to 16 gal. per hour, with a steep drop from 16 to 23, less so from 23 to 30 and only slightly from 30 to 36.

The changes in the formation of toluene are less marked and almost a constant increment of per cent of toluene is to be noted between the rates 16 to 30 gal. per hour. A slight falling off of toluene was found to occur at the rate of 12 gal. per hour. This would indicate that the toluene decomposed more rapidly to form benzene.⁴ The maximum formation of 13.8 per cent of toluene occurred at rate of oil flow of 16 gal. per hour.

The formation of xylene is much less than either toluene or benzene with one exception, at 36 gal. per hour. This rate gave the least decomposition of the starting oil. The maximum formation of 5.9 per cent of xylene occurred at 16 gal. per hour.

The conclusion drawn from these data is that as the initial oil vapors are allowed to remain in the cracking zone increasing lengths of time, the formation of xylene and toluene decrease and benzene increases to the maximum. The maximum of benzene was found to be 26.3 per cent at twelve gal. per hour, while the maximum for toluene was 13.8 and 5.9 per cent for xylene both at the rate of 16 gal. per hour. This brings out the control possible for the maximum formation of the hydrocarbon desired in the recovered oil by change of the time factor.

C. THE EFFECT OF RATE OF OIL FLOW ON THE FORMATION OF BENZENE, TOLUENE AND XYLENE ON THE BASIS OF OIL USED

Industrially the important fact is the production of maximum per cents of the most valuable aromatic hy-

¹Ibid.²Trittman and Egloff, Jour. Ind. Eng. Chem., 7, 481, 1915.³Egloff and Twomey, Jour. Phys. Chem., 20, 121, 1916.⁴Trittman, Brown, and Egloff, Jour. Ind. Eng. Chem., 7, 481, 1915.

drocarbons, benzene, toluene and xylene on the basis of oil used for their production.

In the graph resulting on the basis of oil used two factors are considered, the per cent of aromatic compound in the recovered oil and the per cent of the recovered oil.

In contradistinction to the curves for the aromatic compounds in the recovered oil the curves on the basis of oil used for benzene, toluene and xylene all show a

FIG. 3—THE EFFECT OF RATE OF OIL FLOW ON THE FORMATION OF BENZENE, TOLUENE AND XYLENE ON THE BASIS OF THE OIL USED

maximum but not under the same time factor or rate of oil flow.

The difference between the two sets of graphs lies in the fact that as the time factor increases, the percentage of aromatic formation increases while the per cent of recovered oil decreases.

FIG. 4—THE EFFECT OF RATE OF OIL FLOW ON THE DISTILLATE TO 170° C. AND THE SPECIFIC GRAVITY OF THE DISTILLATE

Up to a certain point illustrated in the rate of oil flow for the different maxima shown, the per cent of the aromatic formation increased more rapidly than the per cent of the recovered oil decreased. With this factor influencing more than the latter, the per cent of the aromatic compounds on the basis of the oil used increased.

As the rate is further decreased the decomposition of the initial oil progresses more rapidly than the formation of the aromatics. A combination of these two factors brings about a maximum in the curve for aromatic formation.

In the recovered oil the formation of benzene, toluene, and xylene show different velocities of formation, with increase of the time factor. The maximum for benzene of 6.6 per cent on the basis of oil used was at the rate of 16 gal. per hour, or 3' 45" per gallon of oil vaporized in the heated zone. For toluene the maximum of 4.1 per cent was at the rate of oil flow of 16 and 23 gal. per hour, or expressed as actual time 3' 45" and 2' 36" per gal. of oil vaporized. Xylene gave a maximum of 2.4 per cent at 23 gal. per hour or 2' 36" per gal. of oil in the vapor state.

The graph is valuable in indicating the best conditions of oil rate at constant condition of temperature

FIG. 5—THE EFFECT OF RATE OF OIL FLOW ON THE SPECIFIC GRAVITY OF THE BENZENE, TOLUENE AND XYLENE CUTS AT 15.5° C.—15.5° C.

700 deg. C. and 150 lb. pressure, for the formation of the aromatic hydrocarbons, benzene, toluene and xylene.

D.—THE EFFECT OF RATE OF OIL FLOW ON THE DISTILLATE TO 170 DEG. C. AND THE SPECIFIC GRAVITY OF THE DISTILLATE

The effect of rate of oil flow upon the distillate to 170 deg. C. is shown in Fig. 4 and indicates that as the time factor increases the percentage increases to a maximum and then decreases. The maximum formation of distillate to 170 deg. C. occurred at 16 gal. per hour and least at 36. The falling off at 12 gal. per hour is readily explainable upon the basis of an increased formation of polycyclic aromatic compounds which have higher boiling points than the derivatives of the benzene series.

The specific gravity of the distillate increases with increase of the time factor to the maximum of 0.875

which is clear indication that the distillate is composed practically of pure aromatic hydrocarbons.¹² At the lower specific gravities mixtures of paraffins, olefins and aromatic hydrocarbons are present, while increase of specific gravity indicates increase of aromatic compounds.

E.—THE EFFECT OF RATE OF OIL FLOW ON THE SPECIFIC GRAVITY OF THE BENZENE, TOLUENE AND XYLENE CUTS AT 15.5 DEG./15.5 DEG. C.

As the time factor increases from 2 to 5 minutes in which 1 gal. of oil in the vapor state is subjected to the heated zone of the tube, the purity of the cuts of benzene, toluene, and xylene increases until at the longest period of time, 12 gal. per hour of oil flow, almost pure benzene, toluene and xylene results from the cracking conditions of the experiment.

A specific gravity of 0.876 for benzene, 0.872 for toluene and 0.871 for the xylene cuts gives practically pure compounds which are readily separated by fractional distillation and clean up readily upon treatment with concentrated sulphuric acid.

In the other cuts with lower specific gravities a mixture of low boiling aliphatic hydrocarbons of the paraffin and olefin type are present, mixed with the aromatic hydrocarbons, benzene, toluene and xylene. The low boiling aliphatic hydrocarbons can readily be used for motor fuel either alone or blending with uncracked gasoline.

An idea of the purity of the distillation cuts from the specific gravity¹³ values, a comparison of the average gravity of the aliphatic hydrocarbons which have boiling points around those of benzene, toluene and xylene are given the following table:

	Average Spec. Grav. Aliphatic Compounds	Spec. Grav. Aromatics
Benzene cut 0° to 95° C.	0.72	0.881
Toluene cut 95° to 120° C.	0.73	0.871
Xylene cut 120° to 150° C.	0.76	0.869

The data indicate the changes produced upon increasing the time factor and that as the time of reaction is increased benzene, toluene and xylene relatively free from the aliphatic hydrocarbons of the paraffin and olefin type are formed.

F.—THE EFFECT OF RATE OF OIL FLOW UPON THE DISTILLATE FROM THE RECOVERED OIL ABOVE 170 DEG. C.

AS SHOWN BY DISTILLATION CUTS AND SPECIFIC GRAVITY

As the time factor increased the recovered oil was mainly aromatic in character.

At 12 and 16 gal. per hour the cuts from 170 deg. C. to tar gave naphthalene and anthracene, as shown by their appearance as solids in the cuts.

As the time of reaction decreased the polycyclic aromatic compounds decreased to zero.

It is of interest to note that as the time factor decreased the formation of tar or pitch decreased in the distillate above 170 deg. C. The mixture above 170 deg. C. is an extremely complex system and no regularity appears to be present judging from Fig. 6.

A minimum occurs in the cut from 170 deg. C. to 270 deg. C. Two maxima appear in the cut from 230 deg. C. to 270 deg. C., while the same appears to be true of the cut to tar.

The per cent of tar decreased with increase of rate of oil flow.

SUMMARY

1. The effect of the time factor or rate of oil flow has been studied at a constant temperature of 700 deg. C.

and 150 lb. pressure and rates of 12, 16, 23, 30 and 36 gal. per hour, for the formation of the aromatic hydrocarbons benzene, toluene and xylene from a paraffin base oil.

2. (a) As the time factor increased the per cent of recovered oil decreased from 65.5 to 17.5 per cent. The time factor is analogous to the effect of increasing the temperature of decomposition of the starting oil.

(b) Increase of the time factor increases the specific gravity of the recovered oil from 0.879 to 0.978/15.5 deg. C. The same phenomenon takes place when the temperature of thermolization of an oil is increased.

3. The maximum per cent of 26.3 of benzene in the recovered oil was found to be at the rate of 12 gal. per hour. The benzene formation increased with decrease

FIG. 6—THE EFFECT OF RATE OF OIL FLOW ON THE DISTILLATION CUTS 170°—230° C., 230°—270° C., 270° TO TAR, AND TAR

of rate of oil flow. The maximum percentages of 13.8 per cent toluene and 5.9 per cent of xylene were both obtained at the rate of 16 gal. per hour. Toluene and xylene showed an increase and then decrease, in their formation, while benzene increased continuously with increase of the time factor within the range of these experiments.

4. The maximum 6.6 per cent of benzene on the basis of oil used was obtained at 12 gal. per hour. The maximum for toluene of 4.1 was found at rates of oil flow 16 and 23 gal. per hour. Maximum formation of xylene of 2.4 per cent at 23 gal. per hour resulted at the temperature of the experiments 700 deg. C. and 150 lb. per square inch.

5. The per cent of distillate increased with increase of the time factor to a maximum of 44.7 per cent and then decreased. The specific gravity of the distillate to 170 deg. C. increased to 0.875 which indicated practically pure aromatic compounds of benzene, toluene and xylene present. The lower specific gravity of the distillate gave mixtures of aliphatic and aromatic hydrocarbons.

6. The specific gravity of the benzene, toluene and xylene cuts indicated the varying amounts of mixtures of paraffins, ethylene and aromatic series of hydrocarbons present. At the rate of 12 gal. per hour maximum purity of the cuts was obtained. Practically pure benzene, toluene and xylene were obtained from a paraffin base oil under these conditions of the experiment.

¹³Rittman, Twomey and Egloff, Met. and Chem. Eng. 13, 682, 1916.

7. No regularity is apparent in the distillation cuts above 170 deg. C. with exception of the tar or pitch formation. Pitch formation decreased with increase of rate of oil flow.

8. Under the conditions of the experiments a maximum total of 12.5 gal. of the aromatic compounds benzene, toluene and xylene were obtained from 100 gal. of oil used, at rate of 16 gal. per hour, temperature of 700 deg. C. and 150 lb. pressure per square inch.

Notes from the Palmer Physical Laboratory

Maximum Watt-Dissipation is Still Air from Nickel Wire and Other Data

BY E. S. NORTHRUP

In the tests to be described the objects held in view were: a—To determine the watts per cm² dissipated in still air from the surface of pure nickel wires with circular cross-section when raised by the passage through them of the electric current to their melting temperature and to observe how this quantity depends upon the diameter of the wire.

b—To find the per cent elongation of a nickel wire when raised from room temperature to its melting temperature.

c—To ascertain the carrying capacity in amperes of nickel wires of different diameters when raised by the passage of the current to the melting point, the wires being in still air and lying horizontal.

d—To find the resistivity of pure nickel when at a temperature just below melting.

For obtaining the above information from a single experiment the device and electrical circuits shown in Fig. 1 were devised.

The wire to be tested was stretched between two binding posts *pp'*. These posts were mounted on a board *B* covered on the top side with asbestos sheet for protection against burning. A spring *S* was hooked to the wire at its middle point, which would raise it up when it increased in length on heating by an amount *h*. The height *h* by which the spring raises the wire was measured with a steel scale. Then from a knowledge of the length *l* and the height *h* the length *l*₁ is easily calculated and consequently the percentage increase in length

may be at once determined from the relation $\frac{l_1 - l}{l} \times 100 =$

per cent increase in length. Provision for heating the wire till it reached its melting point and broke was made by passing through it alternating current derived from a transformer with voltage tap-off points, the cur-

rent being further regulated with a control rheostat. A wattmeter was introduced in the circuit and also an ammeter in the manner clearly shown in the figure.

Since the melting point of pure nickel is accurately known, namely, 1452 deg. C., it is evident that if the current through the wire is slowly increased until the wire melts and the circuit opens, its temperature at this moment must be very approximately the melting temperature of nickel. If furthermore, the length and diameter of the wire is known and the wattmeter and the ammeter are read just before or at the instant that the wire melts and the height *h* be also measured, all necessary facts are known for calculating; the per cent increase in length of the wire in being raised from room temperature to its melting point, the watts being dissipated per cm² from its surface when at its melting temperature, the maximum number of amperes which it can carry in still air and the resistivity of nickel, just as it reaches its melting point.

The resistivity of the wire is given by the formula

$$P = \frac{\pi r^2 W}{L F} = \text{resistivity of nickel at melting temperature.}$$

In this formula *r* is the radius of the wire obtained with micrometer callipers and *L* its length. Strictly speaking *L* should be taken as the length which the wire has attained at the moment of melting, but the error is very slight if the distance between the binding posts *pp'* is taken as the length of the wire. This distance was in all cases 50 cm. *W* is the watts read on the wattmeter and *I* the current read on the ammeter.

In obtaining the data the writer was assisted by several students. He is indebted to Mr. H. F. Porter for working up the data into convenient form for exposition.

Wires of four different sizes were tested and where in the second, seventh and eighth columns of the table of results two figures appear these represent the figures obtained from two independent experiments made on wire of the same size.

All the essential data and results which were obtained are embodied in the table given below.

DATA AND RESULTS
All wires 50 cm. long between binding posts. Ni melts at 1452° C.

Wire Diameter in Cms.	Total Dissipation Watts	Rate of Spring in Cms.	Total Length of Wire in Cms.	Per Cent Increase in Length	Total Surface Area in Sq. Cms.	Watt/cm ²	Max. Carried Amperes	Resistivity at Melting Point, Microhms	Times Increase in Resistivity
0.0246	270	6.5	1.6	3.22	4.003	67.5	6.21	61.5	6.7
0.051	475 465	5.8 5.8	1.32	3.22	8.273	56.75 56.22	16.7 16.5		
0.0755	650				12.28	52.74	29.15		
						52.12	28.70		
0.109	900 940				102.3	32.26 32.71	63.0 63.3		

Precision attained probably between 1 and 2 per cent.

The following points may be mentioned: The results give the very upper limits of current and watt-carrying capacity of a rheostat constructed in the very common form of winding a wire in a spiral. Possibly nichrome, which is said to melt at a slightly higher temperature than nickel, would carry a little more.

The results give the very maximum of watt dissipation in still air of straight horizontally stretched nickel wires. In round numbers one may say that 50 watts to the square centimeter of heat dissipating surface is about the ordinary limit of wires having the high melting point of nickel. Of course, if resistance wires are wound on cylinders as in resistance furnaces and packed round with heat insulating material they will dissipate but a small fraction of the watts and carry but a small fraction of the current given in the above table of results which apply only to the condition of

FIG. 1. EXPERIMENTAL ARRANGEMENT

the wire being stretched in a horizontal position in still air.

It is very interesting to note that wires of small diameter can get rid of their heat per square centimeter at about twice the rate that a wire of large diameter can.

The method above described would not be applicable with any degree of precision to wires made of metals which oxidize rapidly, such as copper. However, the oxidation might be prevented by plating wires of a readily oxidizable metal with nickel.

The increase in the resistivity of nickel in passing to the melting point from room temperature is about 6.7 times its resistivity at room temperature. It is highly probable that on melting the resistivity suddenly doubles, though I am not aware that this determination has been made in the case of nickel.

The per cent increase in the length of the wire was 3.22, an amount quite sufficient to cause a nickel wire wound tightly on a cylinder of refractory material to loosen up badly when brought to a high temperature. It is this fact that makes it generally unsatisfactory to endeavor to secure furnace resistance wires firmly on a refractory cylinder by covering them over with a refractory cement. The cement generally scales off, due to the expansion of the wire.

Notes on Copper Smelting at the United Verde Copper Company

(Editorial Correspondence)

The new smelting plant of the United Verde Copper Company, erected in 1914-15, is situated at Clarkdale, Ariz., in the valley of the Verde River, about 5 miles distant and 2000 ft. below the town of Jerome, where the old plant was situated.

The Clarkdale smelter is equipped for both reverberatory and blast-furnace smelting by the most approved modern methods, and although erected primarily to treat the company's own ores, it is available for smelting such custom ores as are offered from the district. Blast-furnace smelting is the more important operation, with regard to tonnage treated, but the reverberatory furnaces are a valuable adjunct for smelting fine ore and flue-dust.

FIG. 1—GENERAL VIEW UNITED VERDE SMELTER, CLARKDALE, ARIZ.

FIG. 2—SAMPLE MILL, UNITED VERDE SMELTER

The company's mine affords three types of ore, making a mixture that is largely self-fluxing, and in addition thereto a high grade of limestone is obtained from a local deposit. Typical analyses of the three classes of ore are given in Table I. The most important is a heavy sulphide, well suited to blast-furnace treatment. The second type is a more silicious sulphide, and the third an oxidized highly silicious ore. At the smelter these ores are designated as iron, silica and oxide respectively. The last is used not only as a constituent of the blast-furnace charge, but portions of it are so highly silicious as to be useful for converter flux and reverberatory fettling. An important characteristic of the United Verde ore is its remarkable freedom from arsenic and antimony.

Blast Furnace Smelting

An uncommon feature of the blast furnaces is the Giroux hot-blast top, in which air is preheated before going to the tuyeres. This was a characteristic of the furnaces at the old plant at Jerome and has been retained. The first cost of construction is, of course, greater than for furnaces with brick superstructure, and additional power is required to force the air through the pipes; but the company's metallurgists are convinced that definite advantages accrue from this construction in the increased temperature of the blast and convenience of operation. The economy and efficiency of hot blast have long been realized in iron smelting, where the inflammable gases evolved from the furnace are used as fuel in preheating air. Since no such gases are evolved in any quantity in copper matting, economy of heat in smelting is sought by preheating the blast in separate U-pipe stoves or in specially constructed furnace tops like the Giroux. The advantages claimed for hot blast are reduction in the percentage of coke required, conservation of heat and acceleration of reaction between the components of the charge. With the Giroux construction the charge may be smelted with hot top without risk of damaging the furnace superstructure.

Table II shows a typical blast-furnace performance on run-of-mine ore for a twenty-four hour period. Blast pressure is 30 oz. The coke used contains 22 per cent ash, and the quantity averages about 6 per cent of the weight of the charge. Copper on the charge is about 5 per cent and sulphur about 25 per cent. The matte will average 23 per cent copper. A typical slag analysis is given in Table III.

Blast-furnace gases are conducted by two flues from each furnace to a dust chamber running parallel with the furnace building. The interior of this chamber is fitted with baffles that give the gases a tortuous path throughout the entire length. The bulk of the dust is recovered here, and the gases continue through a short flue to the 400-ft. brick-lined steel stack. Analysis of the flue dust is given in Table IV.

Roasting and Reverberatory Smelting

The roasting plant for fine ore comprises six six-hearth, air-cooled Wedge furnaces, 21 ft. 6 in. in diameter, with rabble arms traveling at the rate of about one revolution in two minutes. Auxiliary oil burners are provided which are portable to the several hearth doors. These are for occasional use when the ore is coarse or low in sulphur, or for any other reason not roasting properly. No limestone is added to the furnace charge. Feed will average 28 per cent sulphur and the calcine 8 to 9 per cent. Under these conditions each furnace shows a capacity of 90 tons in twenty-four hours, and the entire battery is operated by a 30-hp. motor. Flue dust is collected in a chamber fitted with plate and wire baffles.

Reverberatory furnaces are 19 ft. wide by 100 ft. long. One of the three is constructed for charging through hoppers arranged above the side walls. The other two are charged through central hoppers in the

FIG. 4—CONVERTER ROOM, UNITED VERDE SMELTER

usual manner but have side hoppers for fettling material. Each furnace has two 700-hp. Stirling waste-heat boilers which, however, can be oil-fired independently of furnace operation.

The furnaces also are oil-fired, using California crude oil under a feed pressure of 60 lb. and at a temperature

of 170 deg. Fahr. Air is delivered to the nozzles at 15 lb. pressure. Reverberatory capacity is in excess of present requirements, but on the completion of a proposed crushing and screening plant at the tunnel mouth a larger quantity of fine ore will require reverberatory treatment.

Analyses of materials charged to the reverberatories are given in Table IV, and a typical reverberatory tonnage for twenty-four hours in Table V. The oil con-

sumed in smelting the 333 tons of charge indicated was 262 bbl., giving a fuel ratio of 0.79 bbl. per ton of solid charge. The quantity of converter slag delivered to the furnace is not recorded, nor are any figures available from which to credit the fuel ratio with heat utilized at the boilers. With this credit applied the fuel consumption would appear much lower. Reverberatory matte is higher grade than that from the blast furnaces, averaging 35 per cent copper.

FIG. 3—400-FT. STEEL STACK, UNITED VERDE SMELTER

Basic Converting

The converting equipment consists of five stands and eight shells of the Great Falls type, 12 ft. in diameter and lined with magnesite. The output is 80 tons of copper per day. Silicious ore used for converter flux has approximately the same composition as that shown for reverberatory fettling in Table IV. Two tons of ore is used in the converters for every ton of copper produced. Air is supplied at 15 lb. pressure from several blowing units, the latest of which is a turbo-blower running at 2500 r.p.m. and having a capacity of 24,000 cu. ft. of free air per minute.

The blister copper produced at the United Verde smelter is 99.25 per cent pure, and as stated before is remarkably free from arsenic and antimony. It is taken from the converters in 10-ton ladles and cast into 365-lb. bars in two casting machines. Converter slag is charged both to the reverberatory furnaces and blast-furnace settlers.

Earlier mention was made of a proposed crushing and screening plant at the mine. The construction of this plant will benefit both blast-furnace and reverberatory operations. For the former it will insure the delivery of raw ore free from fine material, thereby making for increased tonnage, reduction in flue dust, and possibly a lower consumption of coke. For the reverberatories it will afford a supply of material more nearly equal to the present furnace capacity.

Smelting operations of the United Verde Copper Company are under the direction of Mr. Thomas Taylor, superintendent, and Mr. H. N. Thomson, metallurgist.

Some Technical Applications of Capillary and Electrocapillary Chemistry*

BY W. C. MCC. LEWIS, M. A., D. SC.

Capillary chemistry, as the name suggests, deals with phenomena which occur at the surface or interface which separates two phases. The term "surface" or "interface," in this connection, does not refer to the mathematical concept of a surface (which has no physical existence). What is meant is the very thin interfacial layer caused by the interpenetration of both phases, which extends to a very slight depth, not exceeding the effective range of molecular attractions, that is in all probability a few millionths of a centimeter.

It might be thought that effects which are limited to such dimensions would never play any significant rôle in physico-chemical phenomena. This is true up to a certain point. Given the proper conditions, however, surface effects play not only a significant, but even a decisive part in the observed phenomena. The necessary condition is that the surface shall be large compared to the mass or bulk of at least one of the phases. Under this condition it is to be expected that the force known as surface tension may lead to the production of phenomena not observable when the phases which constitute the system are present in bulk.

To illustrate the point, let us consider the phenomenon of adsorption. Suppose we have an aqueous solution of, say, sugar in contact with an oil in which both sugar and water are insoluble; then, if the presence of the sugar modifies the interfacial tension between the oil and the water, it will be found that the concentration of the sugar in the interfacial layer is not identical with its concentration in the bulk of the solution. This surface-concentration effect is denoted by the term adsorption to distinguish it from absorption which means the distribution of the solute throughout the entire bulk of a phase.

The phenomenon of adsorption is one of the most important and characteristic features of capillary chemistry. It was first put on a sound theoretical basis by Willard Gibbs, who showed that the phenomenon depended upon the effect produced by the dissolved substance upon the value of the interfacial tension between the two immiscible phases. Gibbs proved by thermodynamic means that if a dissolved substance was capable of lowering the interfacial tension, then the substance would be positively adsorbed at the interface; that is, its concentration in the surface layer would be greater than its average concentration in the bulk of the same phase. On the other hand, if the dissolved substance was capable of raising the interfacial tension it would suffer adsorption at the surface; that is, its surface concentration would be less than its average concentration in the bulk of the phase.

One can test Gibbs' expression by forming an emulsion of, say, hydrocarbon oil in an aqueous solution of some substance which is quite insoluble in the oil in the ordinary sense, but which has the property of lowering the interfacial tension oil-water. It will be found that the concentration of the dissolved substance throughout the bulk of the water is less than its concentration previous to the formation of the large interface produced by emulsifying the oil. That is, some of the substance is now closely adhering to the oil-water interface at a higher concentration than that possessed by it in the bulk of the water. The bulk concentration has consequently been depleted to allow of the adsorption layer being formed. Two conditions are postulated in Gibbs' deduction: first, the phenomenon must be reversible; that is, if the concentration of the solute in the bulk of the aqueous phase be diminished the surface concentration must likewise diminish; and secondly, the bulk concentration must not exceed the limits of applicability of the perfect gas laws.

The reference of the term emulsions suggests two other kinds of systems very similar in nature and behavior, namely, suspensions and colloidal solutions. Suspensions, emulsions, and colloidal solutions are all ultimately governed by the same laws. They are all fine-grained systems, possessing large interfacial area compared to the mass of the disperse phase. Suspensions represent systems having the largest size of particles (diameter approximately 10^{-4} cm.), emulsions come next with diameter of the order 10^{-5} cm., and colloidal solutions represent the highest stage of subdivisions, with particles the diameter of which is usually of the order 10^{-6} cm.

It is an important though not easily understood fact that great variation in size of the particles in one and the same system renders the system an unstable one, with the result that the particles, instead of remaining in permanent distribution throughout the liquid medium, agglomerate or coagulate, giving rise to a jelly-like mass, called a gel to distinguish it from the stable suspended state, which is termed the sol.

Since suspensions, emulsions and colloidal solutions are characterized by the possession of large interfacial area, it is obvious that adsorption effects may take place upon the particles of these systems just as in the case of porous bodies possessing large surface area, such as charcoal, textile fabrics, paper, sand, and soil. Suspensions, emulsions, and colloidal solutions possess, in addition, certain well-marked characteristics more particularly associated with the phenomenon of their stability in the disperse or sol form, and the conditions which determine the conversion of the sol into the gel.

The first point is the determination of the average size of particles in a colloidal solution, or what amounts roughly to the same thing, the apparent molecular

*A paper read before the Liverpool Section of the Society of Chemical Industry. From the issue of May 31, 1916, of the *Journal of the Society*.

weight of the colloid in the sol form. From the fact that colloid particles are invisible under a high-power microscope, Bredig inferred that the diameter must be less than 10^{-4} cm. From the fact that colloidal solutions possess the property of polarizing light, Lobry de Bruyn concluded that the diameter could not be less than 5×10^{-6} cm.; that is, of the order 10^{-5} to 10^{-7} cm. Other considerations, also based upon optical effects, have led to the value 5×10^{-6} cm. for the average diameter of colloidal metals. As regards molecular weight, the result of applying the ordinary osmotic expression—which, by the way, seems to be a perfectly justifiable procedure in view of the work of Perrin and others—has led to enormous values: e. g., 5000 for gelatin, 15,000 for albumin in water.

A further point of interest is the so-called Brownian movement, exhibited by suspended particles, and due to the bombardment of the particles by the molecules of the medium. Although this phenomenon is of great theoretical interest, it is not proposed to consider it further in this place, since in the few technical applications of capillary chemistry which it is proposed to deal with later no explicit use of the phenomenon is made.

We may now pass to what is probably the most important phenomenon in connection with colloids, namely, the *electric charge* which the particles possess and the mechanism of *coagulation*, which is intimately connected with the removal of the electric charge. Practically all particles in the stable colloidal or emulsoidal state are electrically charged. In aqueous solution, colloidal metals, sulphides, and oil emulsions are negatively charged, while colloidal hydroxides and many organic substances are positively charged.

The sign of the charge is most conveniently determined by placing the colloidal solution or emulsion in a U-tube fitted with platinum electrodes, and observing the direction of motion of the particles under the applied electromotive force. This movement is termed *cataphoresis*. When the particles arrive at the electrode, which is naturally charged in the opposite sense to that of the particles themselves, the latter are discharged, and coagulate together to form a gelatinous mass at the electrode which is easily distinguishable by the eye.

It is a remarkable fact that the removal of the charge should bring about coagulation. The simplest view of the matter, though probably an inadequate view, is that coagulation is prevented by the electrostatic repulsions of charges of the same sign, and that when the repulsion is removed by the discharge the accidental impacts of the now uncharged particles result in the building up of large aggregates which are precipitated by the action of gravity.

That gravity does not cause the precipitation of individual particles, even apart from their charge, is probably due to the fact of Brownian movement, the particles being retained in suspension in virtue of the bombardments by the molecules of the medium.

A matter of the greatest uncertainty is the problem of the ultimate source of the electric charge, which the particles carry.

We know that colloids can be discharged and coagulated, not only by contact with an oppositely charged electrode, but also by means of electrolytic ions of opposite sign, the coagulating effect of such ions increasing generally with their valency. Thus Al^{+++} ion, which possesses three positive charges, is a better coagulant of a negatively charged colloid, such as colloidal arsenic sulphide, than is Ba^{++} , which carries two positive charges; and this, in turn, is much more effective than a monovalent ion such as Na^{+} .

In view of the fact that ions can bring about dis-

charge, it has been inferred that the charge in the first place was conferred by the adsorption upon the surface of the colloid of one of the ions of the medium, say H^{+} or OH^{-} , when water is the medium. Such a view as this receives considerable support from the behavior of a colloid such as albumin, which has been shown by Hardy to be neutral, or nearly so, in pure water, positively charged in acid solution where H^{+} is in excess, and negatively charged in alkaline solution where OH^{-} is in excess. I am inclined to think, however, that albumin is rather a special case. The difficulty of accepting the ionic-charge view as a sufficient one is evident when it is remembered that colloidal solutions may be obtained in media in which it is difficult to believe that ions exist. Thus Billiter has prepared colloidal platinum in chloroform, in which the colloid is electrically charged; and what is equally remarkable, the charge is a positive one, although in water colloidal platinum is negatively charged. Further, the process of spraying liquids through an orifice into a vacuum, or into a gas, confers a charge upon the particles. This process is hardly distinguishable from the more familiar cases of frictional electricity.

In my opinion, the origin of the charge carried by a colloid or emulsion particle is the same as that which we recognize as frictional electricity. In this connection it is very significant that in general the sign of the charge carried by a particle is determined by the relative values of the dielectric constant of the disperse phase and the medium the phase which possesses the higher dielectric constant being the positively charged one. Now, water is a substance with a characteristically high dielectric constant, and it is to be anticipated, therefore, that in the majority of emulsions and colloidal solutions which contain water the water will be positively charged with respect to the particles; or, what is the same thing, the particles will be negatively charged with respect to the medium. Although one can obtain positively charged colloids in water, it can probably be stated that the majority of colloidal solutions in water contain particles which are negatively charged.

It would be rash, however, to believe that dielectric constant is the only determining factor. Even granting the frictional idea, we are still met with the difficulty of visualizing with any degree of clearness the relative distribution of the opposite charges existing respectively on the particle and upon the neighboring molecules of the medium. The usual view is due to Helmholtz, and is, therefore, spoken of as the "Helmholtz double-layer" theory. According to this, a colloid particle and the surrounding layer of molecules of the medium can be regarded as a small condenser with a certain potential difference between the surface of the colloid and the nearest layer of molecules.

But this does not really take us very far unless we postulate something further about this system. It will be observed that a system represented by a charged colloid particle surrounded by a layer of oppositely charged molecules is, strictly speaking, electrically neutral as far as an external field of force is concerned. An effective charge can only be produced in such a system if there is a certain amount of "give" between the nucleus and the outer layer; and the fact that colloids do move in an electric field is evidence that such a "give" takes place.

Lamb (Phil. Mag., 1888) is practically the only investigator who has attempted to deal quantitatively with this point by introducing a factor called the "facility of slip" into his expression for the potential difference across the "double layer."

It is obvious that any attempts to determine the actual charge carried by a colloid particle are very liable to

error. What we do measure is the much smaller quantity, namely, the *effective* charge, which is dependent upon the magnitude of the facility of slip. If the facility of slip were zero, that is, if there were no "give" between the layers, the colloid-condenser system would possess no effective charge at all, though the true charge upon the particle might be considerable. The results of such determinations have hitherto been very discordant, and we really do not know with any certainty the true charge on a colloid particle.*

Although this is the case with regard to the charge, the value of the potential difference between the colloid particle and the surrounding medium is much more accurately known. We are particularly indebted to E. F. Burton (Phil. Mag. 1906) for having carried out the first quantitative measurements in this direction. As a rough approximation, one may say that the potential difference amounts to 0.05 volt for practically all colloids and emulsions. The determination of this potential has great significance for the phenomenon of coagulation, for it has been found that by addition of a suitable electrolyte it can be reduced to zero, and may even be carried through zero to real values of opposite sign.

The position at which the potential difference is zero has been called by Hardy the isoelectric point, and it was considered that this corresponded to the optimum condition for coagulation, or what is the same thing, at the isoelectric point the colloid is most unstable. Although this is nearly true, the actual coincidence of iso electric point and maximum instability has been called in question. This problem is, therefore, in a state of considerable uncertainty.

A similarly unsatisfactory state of things exists in relation to the discharging effect produced by ions when we come to examine the phenomenon closely. It is easy to conceive of a positive ion, such as Al^{+++} being absorbed upon a negative colloid and discharging it, but what rôle are we to attribute to the negative iron originally associated with the Al^{+++} ion? It is known, for example, that aluminum sulphate possesses a different coagulating power from aluminum chloride—but why? We can only say that we do not know. Even the recent work of Bancroft (Trans. Amer. Electrochem. Soc., 1915, 27, 175), which has increased our knowledge of such phenomena very considerably, does not get us further than the conclusion that there is a specific adsorption effect entering in all cases, specific not only with respect to the ions, but likewise with respect to the colloid. It is clear that an immense field lies untouched in such problems as these.

Before passing from the problem of electric charge and coagulation it is necessary to deal very briefly with the closely allied phenomena of *colloid-protective effect* and *peptonization*. It is well known that a colloidal solution of platinum in water can be rendered much more stable by the addition of a small amount of gelatin. The gelatin acts as a preservative. In this case, one colloid stabilizes or protects the other. In the phenomenon of peptonization we have what may be described as the reverse of coagulation. That is, certain gels may be converted into sols by the action of reagents. Thus the gel hydroxides of zinc, aluminum, and chromium can be converted into the sol form by addition of excess of caustic potash. It is to Bancroft (loc. cit) that we owe the idea that protective effect and peptonization are one and the same thing.

To illustrate the point, a sentence or two may be quoted from a recent paper by Bancroft (l. c.) dealing

with the behavior of mixtures of chromic and ferric salts with excess of alkali: "Hydrous (hydrated) chromic oxide is peptonized by caustic potash, while hydrous ferric oxide is not. If the chromium salt is present in large amount relatively to the iron salt, the ferric hydroxide will absorb the peptonized chromic hydroxide and be peptonized by it, thereby going apparently into solution. If the ferric salt is present in excess it will absorb the peptonized chromic hydroxide, carrying it out of the liquid phase. It is to be noticed that the chromic hydroxide, when in excess, acts as a so-called protective colloid to the iron hydroxide."

There still remains one other phenomenon of capillary chemistry, the importance of which is very great, both from the scientific and technical standpoint, namely, the phenomenon of *electro-osmosis*, or *endosmosis*. By electro-osmosis is meant the movement of a liquid through a membrane or through a capillary tube toward one of the electrodes when the membrane or tube is placed in an electric field of force between the two electrodes. The phenomenon is due to the fact that at the glass-liquid interface there is a potential difference, due to charges of opposite sign resident upon the glass, and the neighboring molecules of the liquid. These charges are not rigidly fixed, and can, therefore, slip from one molecule to another, in a sense, parallel to the axis of the tube.

It has long been known that if water be placed in a vessel divided in half by a vertical, porous membrane, and an electrode be placed in each half, then the water will move through the membrane under the influence of the external e.m.f., so that the level rises in one half and falls in the other. This phenomenon is similar to cataphoresis, with this difference: that in cataphoresis the liquid medium remains approximately stationary during the passage of the suspended particles through it, while in electro-osmosis the medium itself moves, the diaphragm being fixed.

From what has been said already regarding the origin and magnitude of the electric charge on colloid particles it is obvious that our knowledge of the phenomenon of electro-osmosis is somewhat unsatisfactory. In this, as in other applications of capillary and electrocapillary chemistry, technical practice is considerably ahead of theory.

Some Applications of Capillary and Electrocapillary Chemistry to Chemical Industry

The following list, which is by no means exhaustive, will serve to illustrate the variety of technical processes in which capillary effects play an important rôle:

- Rubber preparation. Vulcanization.
- Separation of ore constituents.
- Sprayers for crops. Soil fertility.
- Rôle of colloidal iron in plant growth.
- Medicinal emulsions. Milk. Cream formation.
- Beverages. Liquid foods. Enzymes. Inorganic ferments.
- Peptonization. Clotting. Physiological fluids.
- Emulsions for photographic purposes.
- Gums and adhesive materials.
- Inks and marking fluids. Pigments.
- Dyes and dyeing. Bleaching, tanning, staining.
- Paper sizing and coloring. Carbon and other copying papers.
- Soap manufacture and cleansing action.
- De-emulsification of water in steam turbines.
- Filtration processes. Peat drying, etc.
- Sewage treatment. River sludge. Charcoal purifiers.
- Colloidal metals in fused melts. Ruby glass. Opaque glass. Enamel.
- Cement. Mortar. Plaster.

*For a fuller discussion of the problem see the chapter on colloids contained in the author's "System of Physical Chemistry" in Sir William Ramsay's series of text books.

Rôle of colloids in electrolysis.

Contact catalytic processes.

A few of the problems involved in some of the above applications of capillarity will be considered under the following heads: (a) general capillary principles; (b) technically important emulsions and colloidal solutions; (c) adsorption; (d) coagulation; (e) selective adsorption (of ions); (f) protective effect; (g) electro-osmosis.

(a) Application of General Capillary Principles to Certain Technical Problems

As an example, we may consider the theory of wetting and the *determination of wetting power*. This is of great importance, especially in agricultural practice, since it is a determining factor in the efficiency of liquid sprayers. A special case has recently been examined by Cooper and Nuttall (J. Agric. Science, 1915, 7, 219-230). These investigators point out that the efficiency of a spraying liquid is not solely dependent upon the amount of toxic substance present, the wetting power being of equal importance.

The wetting power depends upon the value of the interfacial tension between two phases, this value determining whether a liquid, A, will wet or run over the surface of a second liquid or solid, B. The value of the interfacial tension can be modified by adsorption phenomena, since positive adsorption necessarily accompanies a decrease in tension. The lower the tension the greater the wetting power.

To get efficient spraying it is, therefore, necessary to have present some substance which markedly lowers the tension. For this purpose, soap, or a substance having a "soap basis," is particularly suitable, and is, therefore, recommended by these authors.

(b) Technically Important Emulsions and Colloidal Solutions

One of the most important emulsions we have already referred to in sprayers, or spraying liquids. These usually consist of an oil of some kind emulsified with water which contains a substance possessing toxic properties, such as basic copper salts, in the case of potato spraying to prevent potato blight. In such cases as these the emulsion which is formed by mechanical means is very far from being uniform, and can scarcely be regarded as stable. In the case of medicinal emulsions, such as cod liver oil emulsion, the preparation is carried out with greater care, a much more uniform and therefore more permanent emulsion resulting. Artificial beverages are, for the most part, emulsions or colloidal solutions. Cocoa and coffee, for example, may be regarded as emulsions, tea as a colloidal solution. The production of tannin-free tea depends upon the fact that the colloidal tannin can be coagulated and separated. As regards natural emulsions, the most important of all is, of course, milk. Milk is only a moderately stable emulsion, and in many respects this is a decided advantage, otherwise cream might have remained an unknown commodity.

Another exceedingly important emulsion which occurs naturally is rubber latex. Reference will be made to this later in dealing with its coagulation.

Besides colloidal solutions in which the liquid medium is usually water or aqueous solutions, there are a number of others which are only liquid in the sense of being mobile at relatively high temperatures. I refer to glasses and enamels. Ruby glass, for example, is a very beautiful illustration of a true colloidal solution of extremely high viscosity, the colloid being a metal, the medium a mixture of fused salts. Many such colloidal solutions have been known for centuries. Among recent

preparations of such solutions may be mentioned that of translucent glass. Such substances, however, are of very complex composition, so that while one feels justified in instancing them as examples of the colloidal state it must at the same time be confessed that the knowledge we possess of colloids is far too limited to be of much use in dealing with complex cases and still less with suggesting improvements on rational lines. It would appear that empirical methods must unfortunately be relied on for perhaps a long time yet in such cases, for the lag between theory and practice is unfortunately great.

The question of photographic emulsions will be briefly considered in dealing with electro-osmotic processes.

(c) Technical Applications of Adsorption

Technical processes in which adsorption plays an essential part are very numerous. In the place of first importance one should mention *dyeing* processes. It is now fairly generally recognized that the first stage in such processes is a true adsorptive one. Dyestuffs are generally characterized by exerting a very marked lowering effect upon surface and interfacial tension. It follows therefore from Gibbs' principle that they are largely adsorbed, with the result that in the surface layer (which probably does not exceed 10^{-6} cm. in thickness) the concentration of the dye becomes great, eventually exceeding the limit of solubility which it possesses in the ordinary sense. The result is that precipitation or coagulation takes place and this in many cases is accompanied or succeeded by ordinary chemical combination with certain of the amphoteric substances present in the material to be dyed.

It is clear, of course, that adsorption cannot cover the whole phenomenon, for adsorption in the sense of Gibbs' theory is a reversible process, while dyeing is essentially an irreversible process, the fastness of the dye being dependent upon the fact of irreversibility.

In the case of *tanning* the process is very similar. A reference will be made to tanning later from the standpoint of electro-osmosis. It will be observed that in dyeing and tanning we are dealing primarily with the adsorption of colloidal matter upon a surface, most dyestuffs such as Congo red belonging to the group of so-called "electrolytic colloids," that is the colloidal part functions as an ion (anion).

Bleaching processes, while being fundamentally adsorptive in nature, differ from the preceding cases in that the bleaching agent is not usually a colloid and therefore its effect upon the surface is a better defined chemical process. A bleaching agent such as sodium hypochlorite lowers the surface tension of water and hence is positively adsorbed at the surface.

Surface-adsorption of molecules and ions of electrolytes plays a fundamental rôle in *agricultural problems*. One of the results so far obtained in this very complex subject is the conclusion that the general character of a soil is as much governed by the size of grain, that is, by the surface area of the soil particles, as by their chemical nature. Heavy clay means small porosity, and therefore small surface and small adsorbing power for salts and non-electrolytes dissolved in the water present. The result is that this material is unsatisfactory. The function of adsorption in soils is to retain the soluble salts from being washed away too far from the surface of the ground during heavy rain. The extent to which adsorption occurs depends not only upon the soil but also upon the nature of the fertilizer. The question of the efficiency of fertilizers would lead us too far, but that the problem is fast becoming an exact applied science is very evident. It is clear on general grounds that capillary chemistry plays a great rôle in such prob-

lems, as we have already seen in connection with the theory of wetting, but it is to be feared that many of the workers in this field have not fully realized the significance of capillarity for the processes concerned.

A further important technical application of adsorption is found in the methods of *water and sewage purification* in so far as *filtration* is concerned. The functions of porous substances such as charcoal and sand are so familiar that they need not be considered at length. It is sufficient to point out that capillary adsorption is the fundamental factor, though, as in dyeing and tanning, the irreversibility of the process is an essential, and in so far as irreversibility exists the phenomenon is not covered by the simple capillary theory. Purification problems also come under the head of coagulation of colloids and a brief reference to them will be made there.

Another field in which adsorption plays a part is that of the *cleansing action of soap and the clarification of liquids*, such as wines. In the case of soap there is no doubt that the alkali produced as a result of hydrolysis acts as a peptoniser or emulsifier for the fatty matter which is to be removed, and the intimate contact, which is necessary to attain this, is possibly brought about by the fact that the soap, both unhydrolyzed and as colloid ions, depresses the interfacial tension with the result that adsorption of the soap takes place and capillary wetting occurs easily.

In the case of clarification processes the results of a particular investigation may be cited as illustrative, the object being to find a good clarifying agent for certain wines which would be effective without altering the taste appreciably. According to F. La Marca (see this Journal, 1915, p. 1066), "experiments with nine types of Italian wines indicate that fish glue was the best clarifying agent." The tannin and extract content can be reduced by adsorption upon the fish glue without altering other constituents. "Egg albumen is also an excellent clarifier and does not alter the composition of the wine." Aluminous earth markedly reduces the acid content and also the extract, but not the color or the tannin. "Acidity and color are diminished by charcoal, which also reduces the tannin to a slight extent." The specific effects of adsorption upon surfaces of different nature manifest themselves here very clearly.

(d) Application of Coagulation Principles

Coagulation, as already pointed out, is brought about by removing the electric charges which are situated upon the colloid or emulsion particles and which go to maintain these in a stable sol form. The discharging process is most conveniently carried out by means of electrolytic ions of opposite sign to that possessed by the colloid. The colloid may also be discharged by being carried to an electrode, the discharge at the electrode being presumably quite analogous to the discharge of an ion in ordinary electrolysis. It is of some interest to consider one or two large scale applications of both of these methods of producing coagulation. First of all, coagulation by ions.

A very important application of this is found in one of the methods employed for rectification of current—that is, the transformation of alternating into direct current. In this connection the *aluminum rectifier* is well known. A condenser is placed in the alternating-current line, one plate of the condenser being of aluminum, the space between the plates being filled with an aqueous solution of a salt. On the aluminum plate there is rapidly formed some colloidal aluminum hydroxide, and if this can be made to coagulate and adhere to the plate the current taken off will be unidirectional.

The problem is, therefore, to choose an electrolyte

which will most completely effect the coagulation of the colloid. Since aluminium hydroxide is a positively charged colloid the discharging effect must be brought about by an anion, and further as we have seen the higher valency of the ion the more effective it will be. Thus the salts of monovalent acids—such as nitrates, chlorides, acetates, etc., are inefficient. Salt of divalent acids, such as sulphates, carbonates, and tartrates, are moderately efficient. That is to say, a rectifier containing such divalent salts will rectify current whose voltage does not exceed 30-50 volts. If the current is at a higher voltage the rectification is only very partial and incomplete. Using trivalent radicles such as phosphates, citrates, or borates, the efficiency of the rectifier is much increased, as it is now capable of dealing with a pressure of over 200 volts. It is interesting to note, also, that silicates, though strictly speaking belonging to a divalent acid, are exceedingly efficient, no doubt due to the fact that the coagulation is here itself functioning as a colloidal anion though a clear explanation of the mechanism is wanting.

Obviously much investigation remains to be done. It would be interesting to try other colloidal anions of much greater complexity than colloidal silicate, such, for example, as organic, electrolytic colloids like Congo red. The point as to whether the molecular mass of the coagulation is significant as well as its valency also requires investigation.

Another important application of coagulation is met with in the *de-emulsification of water contaminated with oil*, the oil being in the form of an emulsion. It is an important engineering problem, especially in connection with the forced lubrication in steam turbines, and has been solved with some considerable success by the use of alum. The oil particles are negatively charged and can, therefore, be discharged by a cation of high valency such as Al^{+++} . The alum solution is run slowly into the emulsion, the oil coagulates on the top and may be run off. The result is that a considerable quantity of oil is recovered which would otherwise have run to waste, and at the same time the oil is prevented from fouling the heated parts of the engine. It may be remarked that oils, otherwise very similar, differ much in the ease with which they become emulsified (cf., for example, A. Philip, *Journal Society of Chemical Industry*, 1915, 34, 697).

The next problem to be touched upon is *river sludge formation and sewage precipitation*. The fact that material which remains in suspension as long as the liquid medium is fresh water but is deposited when carried to the mouth of a river where the medium is now salt, obviously suggests that coagulation has been brought about by the sodium and calcium salts of the sea water. When this process goes on for centuries formation of deltas results. As a rule, coagulation of this kind is anything but desirable. In other cases, however, notably when a river overflows its banks, the result may be beneficial. The fertility of the Nile valley, for example, may be ascribed to this cause, the rich colloidal matter in the river water being precipitated upon the adjacent soil.

In view of the large amount of sewage annually carried down by rivers the question has been raised as to whether it may be possible to recover by means of regulated coagulation some of the valuable fertilizing materials represented by the phosphorus, nitrogen and potassium contained in the sewage. As a matter of fact, an attempt has been made along these lines in Germany, but so far the efficiency is low. It is nevertheless a very important problem. Our present practice of getting rid of sewage somehow can scarcely be the last word on the subject.

As a final illustration of coagulation by chemical means, that is by ions or even by change in the nature of the solvent by large addition of non-electrolyte, a reference may be made to one or two methods for the *coagulation of rubber latex*. A method suggested by Fulton and Macallum (Eng. Pat. 9066 of 1914) depends as far as I see upon the change in the nature of the medium. The latex suspended in water is treated with aldehydes or ketones other than formaldehyde. As an example 80-90 parts of water are added to 10-20 parts of aldehyde or ketone and the solution may be used with about half its volume of latex which is preferably sprayed over the coagulant. An alternative method of treatment which causes coagulation and at the same time sterilizes the rubber is that proposed by S. C. Davidson (Eng. Pat. 22,138 of 1914). A solution of one part of sodium thiosulphate in 16 parts "alkalised cresol," that is, a solution of cresylic acid in aqueous sodium or potassium hydroxide, is stirred into Hevea latex in the proportion of 1 to 5 per cent. The latex is allowed to stand for 24 hours, and is then coagulated by means of a 1 to 2 per cent solution of sulphuric acid. Other acids, such as acetic, trichloroacetic, or hydrochloric may be used. The SO_2 evolved on addition of the coagulating acid possesses a preservative effect upon the rubber.

It is somewhat obscure why it should be necessary to allow the latex to remain so long in contact with the thiosulphate. The thiosulphuric acid may, of course, exert an incipient coagulating action, or it may be that the thiosulphate requires this time to take the place of other salts already adsorbed upon the latex particles. That is to say, it may be a case of preferential or selective adsorption. I have no idea as to how efficient this actual process may be. It serves, however, to indicate how much purely scientific work remains to be done in order to supply us with a larger number of general principles which would serve as guides in this or other colloid problems.

Let us turn now to the alternative method of colloid coagulation by bringing the colloid directly into contact with an oppositely charged metal electrode. This has had up to the present less utility than the ionic method. De-emulsification may be easily effected upon the laboratory scale, but I do not know if it would compare with the alum method on the large scale. The method, however, has been employed for sewage treatment. According to A. M. Williamson (Trans. Amer. Electrochem. Soc., 1915, 27, 193) an installation in America deals with as much as a million gallons of sewage per day. On general grounds one would think that the electrical method should be efficient in that all the colloidal material would automatically separate itself at both electrodes according to the sign of the charge. The method would, however, be more economic of current the smaller the content of electrolytic salts present.

(e) Selective Adsorption

This principle has been made use of in a method proposed for the *separation of radioactive salts* (Ges. für Elektro-Osmose, Eng. Pat. 10,083 of 1914). The salts are in a state of adsorption upon colloid material, this condition being the result of a preliminary treatment. The point is to remove the adsorbed radium salts as completely as possible from the colloid material and from other salts, e.g., barium. This is effected by adding to the colloidal solution certain other salts at suitable concentration. These salts are preferentially taken up by the colloid, the radium salt thus passing into solution.

By way of illustration, a MnO_2 adsorption product of Ra and Ba in a fine state of subdivision is boiled

with NH_4Cl solution of certain strength and the solution filtered. On analysis it is found that the solid matter contains 32.7 per cent of the Ba and 64.7 per cent of the Ra originally present. That is, a certain amount of separation of Ra and Ba has been effected. Although a single run leads only to a partial separation the method is interesting and suggestive.

(f) Application of the "Protective" Effect

Reference has already been made to the protective and preservative action of gelatin upon colloidal platinum. In a process patented by the Gesellschaft für Elektro-Osmose (Eng. Pat. 9261 of 1914), the object of which is to *prepare stable colloidal solutions of metals* in general, use is made of *colloidal silicic acid* as the protective colloid. The silicic acid is obtained in a pure state by a method which will be referred to later.

As an example of the procedure adopted, a metal salt, i.e., a silver or gold salt, is reduced by a suitable reagent such as hydrazine hydrate in presence of the silicic acid. A stable solution of silver or gold results, which is purified from the electrolytes by electrolysis. In a later patent (Eng. Pat. 15,267 of 1914) it is claimed that the protective effect of silicic acid can be extended to the preparation of stable metals prepared by Bredig's sparking method, the instance quoted being nickel. Further applications of the salt-reduction method in presence of silicic acid deal with the preparation of colloidal selenium, palladium and platinum. It would appear, therefore, that the method is a fairly general one.

A further instance of protective effect is to be found in a process for *sizing and coloring parchment paper* (E. Fues, Eng. Pat. 19,816 of 1914). A solution which contains both an acid and a basic dyestuff may in general be regarded as an unstable one. In the presence of some size, however, precipitation can be prevented, the size acting as a protective colloid. The mixture of dyestuffs can therefore be successfully applied, in this case, to the paper.

(g) Applications of Electro-osmosis

This is one of the most important branches of applied electro-capillary chemistry. As an example of a general type of problem to which electro-osmosis is applicable one may instance *filter press* work. In this connection F. Ulzer (Z. angew. Chem., 1915, 28, i. 308), describes a process whereby filtration of liquids containing very fine particles can be made without clogging the filter cloth. The filter is of the usual form, consisting of a number of chambers in each of which electrodes are placed. The chambers are first filled with liquid, the current is passed, and the suspended matter wanders to one or other of the electrodes, becomes electrically discharged, and is deposited. The liquid can now be made to pass with relative ease through the filter cloth. Clogging of the latter is thus largely diminished, and hence excessive pressure is not required. The author claims that the method separates the finest particles from liquids and can be used for mineral colors, dyestuffs, barium sulphate, and other suspensions. Strictly speaking, the process is an illustration of cataphoresis and coagulation rather than electro-osmosis, but the arrangement is very similar to that employed in electro-osmotic problems generally.

A second instance is the application of electro-osmosis to the preparation of pure colloids, the case in point being the preparation of *colloidal silicic acid* of low molecular weight, that is, in a state of fine subdivision (Ges. für Elektro-Osmose, Eng. Pat. 9273 of 1914). To begin with, an alkali silicate solution of 5-10 per cent strength is placed in an anode compartment, the electrodes being preferably perforated. When the prod-

uct is to be used medically the anode consists of platinum gauze. Brass wire net serves as the cathode, the electrodes being separated by an electrically neutral membrane, consisting of carborundum and corundum. The process begins with low voltage, which is ultimately raised to 60–70 volts to remove all the alkali from the compartment. The colloidal silicic acid negatively charged,* is precipitated at the anode, the sodium leaving the compartment. Traces of foreign acids present with the silica are removed by transferring the solution to a vessel serving as a cathode and electrolyzing, the anode being surrounded by parchment.

A further illustration of the applicability of electro-osmosis deals with the *tanning of hides and impregnation of similar materials*. In the usual method of tanning the material is brought into contact with the tanning liquid under suitable conditions of concentration and temperature, and allowed to remain in contact for a length of time. In the present process (Ges. für Elektro-Osmose, Eng. Pat. 19,849 of 1914) the tanning action is accelerated and possibly improved by bringing the tanning colloid into very close contact with the hide by electrical means. The hide is kept at a suitable potential, positive or negative, and the tanning substance, which is naturally charged, moves up to and is discharged upon the surface. A few details are given in the abstract (this J., 1915, 34, 1021), and are as follows:

"Hide is tanned by electro-osmosis by utilizing the material to be treated as a partition, without fitting it tightly to the walls, to divide the space between suitable diaphragms, the latter being so selected that the active constituents cannot migrate through them, whereas substances affecting the osmotic action unfavorably pass through and are separated from the liquid. Constituents which hinder or delay the process are removed from the hides or skins electro-osmotically by desorption before the actual tanning. During treatment the hides or skins are caused to acquire automatically a potential suitable for the tanning substances used; with tannin this must be of an electro-positive character, with chromium compounds, electro-negative."

As a final example of electro-osmosis we may briefly consider the manufacture of *gelatin for photographic emulsions* (Ges. für Elektro-Osmose, Eng. Pats. 21,448 and 21,484 of 1914). The object is to get a gelatin free from fat and from mineral and reducing constituents. The procedure is as follows: A solution of gelatin inclosed between electrically indifferent diaphragms is subjected to an external voltage. The inorganic ions migrate through the diaphragms in the ordinary way and so are removed. At the same time any albuminoid bodies are coagulated and can be mechanically separated off. The resulting gelatin is thus free from turbidity which sometimes manifests itself owing to the presence of albumin. Exactly the same procedure is applicable to the manufacture of *high grade glue*. Modifications may be introduced in the form of electrically charged diaphragms for the separation of other constituents, thereby yielding a very pure product.

From the survey given above it is evident that the subject of capillary and electrocapillary chemistry is one of great magnitude and importance both from the scientific and from the technical aspects. In the present situation it is plain that technical application has considerably outrun theory, and if future industrial development is not simply to be on empirical lines, it is essential that scientific investigation must be greatly accelerated. At the present time capillary chemistry does not occupy the place it should in our University

curricula. But as things stand it is impossible to deal with the subject effectively. From the manufacturers' standpoint, a serious lesson might be drawn from the activities of a single German firm, the Gesellschaft für Elektro-Osmose, from whose patents several illustrative examples have been taken. It is fairly evident that such processes can only be dealt with and extended by proper scientific control. It has been repeated *ad nauseam* that this is the only way to advance not only in regard to the applications of capillary chemistry, but in all applied chemistry. It does not, however, appear, even yet, to have been sufficiently realized.

The Electro-Osmosis Laboratory*

The Active Materials and Electrolyte of the Alkaline Storage Battery

BY L. C. TURNOCK

The materials that function electrochemically in the alkaline storage battery and are employed in its manufacture are nickelous hydrate, $\text{Ni}(\text{OH})_2$, for the positive plates, metallic iron containing a small amount of mercuric oxide, HgO , for the negative plates and an aqueous solution of caustic potash containing a small amount of lithium hydrate as electrolyte.

Preparation of Nickelous Hydrate

Shot nickel varying in size from approximately 1/16 to 1/4 in. in diameter is dissolved in sulphuric acid. The process is continuous, more nickel and acid being added as the solution containing the nickel as sulphate is drawn off. The hydrogen gas evolved in the reaction is retained and conducted to a gasometer; it is subsequently employed in the reduction of ferric oxide to metallic iron.

The nickel sulphate solution contains as impurities small amounts of copper, arsenic, antimony and iron. The bulk of the copper is removed electrochemically by shot nickel, while the remainder together with the arsenic and antimony is precipitated out with hydrogen sulphide gas. The solution is filtered and the iron in the filtrate oxidized to the ferric state with bleaching powder or sodium hypochlorite (NaOCl), the former being used most. The solution is carefully neutralized with soda ash, when the iron precipitates out approximately as a basic sulphate.

The filtrate containing the nickel as sulphate is sprayed by gravity into copper-lined wooden or iron tanks containing a 10 to 15-per cent solution of sodium hydrate, which has been previously brought to the boiling point by means of steam coils placed in the bottom of the tanks. The nickel is thrown down as the nickelous hydrate. The function of spraying the nickel sulphate solution into hot caustic soda is to prevent as far as possible the occlusion of any sulphate by the precipitate, thereby minimizing the amount of subsequent washing required to purify the nickelous hydrate.

The clear liquid is drawn off and the $\text{Ni}(\text{OH})_2$, removed as "mud" and filter-pressed by means of wooden filters. The product contains small amounts of sodium sulphate, sodium hydrate, sodium carbonate and water, all of which must be removed. It is placed in pans and dried by steam coils; the temperature is not allowed to exceed 100 deg. C. An analysis of the dried product averages

Water (in vacuum over Sulphuric Acid) ..	1.33%
Nickelous hydrate	52.54%
Sodium Sulphate	30.34%
Sodium Hydrate	12.41%
Sodium Carbonate (from soda ash)	3.30%

*It is not quite clear what sign the charge possesses under these circumstances. Usually SiO_2 sol is negative, but becomes positive in acid solution.

The mass is leached with hot distilled water (steam condensate) ten to twelve times until the wash water shows no test for sulphates, carbonates, nor gives an alkaline reaction. No attempt is made to wash out the impurities from the nickel hydrate "mud." The filter pressing and subsequent steam drying of the product renders it more porous and permits of more efficient washing and in addition the washing is accomplished in a shorter period.

Following the washing of the nickelous hydrate it is dried by steam coils, the temperature not being allowed to go over 100 deg. C. The product is now tested for its electrical capacity (see below) and if found up to standard ground up in 500-lb. batches. Of the screened material that which is desirable comes between 30 and 190 mesh. The allowable limits for acceptance of material is not over 6 per cent through a 190 mesh sieve and not over 15 per cent upon a 30 mesh sieve. All of the ground product generally passes a 20 mesh. The material is now ready for loading into the tubes that constitute the positive plates of the battery.

Preparation of Metallic Iron

The purest iron obtainable (generally a Norway or Swedish product) is employed as a starting product; it shows on analysis traces of manganese, phosphorus, silicon and sulphur with carbon as low as 0.02 to 0.03 per cent. The raw material is placed in lead-lined digesters and treated with sulphuric acid. The gases evolved, consisting of hydrogen, hydrocarbons and hydrogen sulphide are conducted through a purifying train containing sodium hydrate to remove the hydrogen sulphide and chromic acid to remove the hydrocarbons. The hydrogen is conducted into the same gasometer in which is stored the hydrogen obtained as a by-product in the purification of the nickel. The resulting ferrous sulphate solution is drawn off and crystallized and re-crystallized several times, after which the crystals are put into a centrifugal machine to free from the mother liquor and subsequently into rotary driers fired with fuel oil to a temperature of 200 to 300 deg. C.

The dried and slightly calcined ferrous sulphate is placed in muffle furnaces and given an oxidizing roast. The resulting product is ferric oxide (Fe_2O_3), which is leached out with water to remove traces of ferrous sulphate not affected by the roast. After drying the oxide of iron is placed in iron retorts and set in a muffle furnace and reduced to metallic iron by the hydrogen obtained above. As an index to determine when the reduction of the ferric oxide is complete the charge is weighed as put in and the moisture formed in the reaction condensed, collected and weighed.

The vessels containing the metallic iron are removed from the furnace and allowed to cool in an atmosphere of hydrogen gas to prevent almost spontaneous ignition back to the oxide. As a further precaution against reversion back to Fe_2O_3 , a dilute solution of NaOH (to prevent rusting) is run in on top to cover the iron when the pan is opened. The product is allowed to stand five to six hours in the sodium hydrate solution, when it is drained and dried slowly by heat. After grinding and mixing with 6 per cent of yellow oxide of mercury (which is prepared by dissolving mercury in nitric acid and precipitating it out again with NaOH solution) it is ready to be tested for its electrical capacity and if found up to standard loaded into the pockets that make up the negative plates of the battery.

The beneficial action of the mercuric oxide in

maintaining the activity of the iron appears to be more or less empirical in character. It is reduced to metallic mercury during the charging of the battery as is evidenced by the fact that an examination of the sediment in the bottom of the containers of cells that have been in service for some time frequently discloses the presence of appreciable amounts of metallic mercury that have fallen from the pockets. Small amounts of iron oxide that may be present in the iron through an incomplete reduction of the Fe_2O_3 will lower the capacity of the latter; the presence of mercury seems to counteract this detrimental effect. Moreover, metallic mercury will increase the electrical conductivity of the mass.

Preparation of Electrolyte

The electrolyte employed is made up according to two sets of specifications. One calls for "first" electrolyte, which goes into the cells after assembly, and consists of an aqueous solution of potassium hydroxide (21 per cent by weight) containing 50 grams of lithium hydrate per liter of finished electrolyte. This amount of lithium hydrate represents its maximum concentration in a 21 per cent KOH solution at 24 deg. C. The specific gravity of "first" electrolyte is about 1.230 at 20 deg. C.

The second specifications call for "renewal" electrolyte, which is supplied for renewal after the cells have been in more or less continuous service for about a year. It is made up of an aqueous solution of KOH (25 per cent) and 15 grams of LiOH per liter of finished electrolyte. Fifteen grams of lithium hydrate, likewise, represents the maximum concentration in a 25 per cent potassium hydrate solution at 24 deg. C. The total alkalinity of such a solution, computing the LiOH in equivalence of KOH, is 27.8 plus or minus one-half per cent.

The potassium hydroxide employed is an electrolytic product of potassium chloride and is received as a solid in iron drums. It is dissolved and diluted to a 33 per cent solution and subsequently to solutions corresponding to 25 and 21 per cent, respectively. The specific gravity of the solution is employed as a measure of its strength; 21 per cent KOH has a specific gravity of 1.2026 at 17.5 deg. C. and 25 per cent KOH of 1.248 at 20 deg. C.

The lithium is obtained as the carbonate and dissolved in water in large steam-heated iron kettles and treated with lime (CaO) and hot water. The following reaction occurs:

The calcium carbonate is allowed to settle and a solution containing about 4 per cent LiOH is obtained; it is bluish in color and very caustic. The 4 per cent LiOH solution is concentrated down until about a 12 per cent solution is obtained, when it is analyzed for its LiOH content and its gravity taken. The calcium oxide (CaO) is obtained by calcining a very pure grade of limestone in a kiln fired by producer gas and air.

The following example illustrates the method of computing and making up the electrolyte according to specifications:

Given a 33 per cent KOH solution having a specific gravity of 1.320 and 12 per cent LiOH solution having a specific gravity of 1.14.

Required to find the proportion in which to mix the above two solutions in order to obtain a solution containing 21 per cent of KOH and 50 grams of LiOH per liter of finished electrolyte.

Solution.—One liter of 33 per cent KOH contains
 $1.320 \times 1000 \times 0.33 = 435.6$ grams KOH

1 liter of 21 per cent KOH (Sp. Gr. equals 1.202) contains

$1.202 \times 1000 \times 0.21 = 252.42$ grams KOH
Therefore, volume of 33 per cent KOH solution required to supply 252.42 grams of KOH equals
 $252.42/435.6 \times 1000 = 579$ c.c.

1 liter of LiOH solution contains

$1.114 \times 1000 \times 0.12 = 133.68$ grams LiOH
Therefore, volume of 12 per cent LiOH solution required to supply 50 grams of LiOH equals
 $50/133.68 \times 1000 = 374$ c.c.

Hence, specifications for 1 liter of 21 per cent KOH plus 50 grams per liter is

33 per cent KOH.....579 c.c.

12 per cent LiOH.....374 c.c.

Water (supplied).....47 c.c.

The specifications for making up the solution containing 25 per cent KOH plus 15 grams of LiOH per liter is obtained in a similar manner.

While the battery is in service more LiOH appears to enter the plates on discharge than is given out on charge. Inasmuch as the lithium hydrate seems to exercise a beneficial effect upon the battery in proportion to the amount present in the electrolyte, it is desirable to maintain the concentration of the LiOH at a maximum. For this purpose crystals of lithium hydrate (containing about 54 per cent LiOH), and varying in amount from about 9 grams for the smaller sizes of batteries to over 100 grams for the larger types, are placed in the cell after assembling and just before the "first" electrolyte is added.

Testing of the Nickelous Hydrate and Iron for Electrical Capacity

By electrical capacity of the active material is meant the length of time a certain amount of it, loaded into tubes or pockets similar to those constituting the finished plates, will deliver a specified current by the time its potential falls to a certain predetermined value. The selection of this value is entirely arbitrary and is influenced by the electromotive force characteristics of the two electrodes upon discharge and by the performance of motors, or other electrical appliances to be operated, under the decreasing potential gradient of the battery. It is usually selected to conform to conditions encountered commercially and down to which the battery will show its best service; if allowed to fall lower, it will have little or no practical importance.

Theoretically, a cell containing 1.042 grams of iron and 1.725 grams of nickelous hydrate will furnish 1 amp.-hr., but after a discharge of 1 amp.-hr. it will have no capacity, and its potential will have dropped to a value which cannot be utilized at all. Practically, the battery must have enough excess active material in its construction to insure its potential not falling below a certain arbitrary value while discharging at a certain desired rate and immediately after it has delivered its predetermined capacity in ampere-hours.

Another important factor which affects the available capacity of the battery is temperature. The potential of the battery when delivering its normal rate current is a function of its internal resistance and decreases with increase of resistance. A rise in temperature, however, will decrease the internal resistance and thereby allow of a greater ampere-hour output before the cell will have reached the predetermined cut-off voltage. Consequently, in determining the electrical capacity of the nickel hydrate and iron it is essential that the temperature at which the test is made is the same as that under which the

standard test was made. In order to fulfil the requirement that the cell will not drop below a certain potential before it delivers its rated output, approximately 4.64 times as much Ni(OH)₂ and 5.78 times as much iron are used in the construction of the different plates as the theoretical minimum.

To determine whether or not the active material as manufactured is standard in capacity, tests are made with miniature cells. Those for testing the hydrate of nickel are composed of one tube loaded with the hydrate under question and two pockets, containing some standard iron, mounted on either side of the hydrate tube. Those for testing the iron consist of one pocket containing the iron under question together with two tubes, one mounted on either side of the iron pocket, containing some standard nickel hydrate.

The nickel hydrate is placed into a standard-size tube by an automatic loading machine, which alternately adds and tamps in the hydrate of nickel and flake nickel (very thin squares of metallic nickel about 0.00004 in. thick and 1/16 in. on the edge). The weights of both entering the tube are noted; the flake nickel averages from 13 to 14 per cent of the weight of the total contents.

The electrolyte employed for the test cells is a 21 per cent KOH solution containing 11.2 grams of LiOH per liter of finished electrolyte. Based on their relative capacities the amount of electrolyte employed in the test cells is greater than that used in the commercial sizes; hence, an electrolyte containing less lithium hydrate is employed.

The charging and discharging rates used represent practically the same current density as that recommended for the larger types.

A loaded tube, 3 in. in length, will contain about 7.75 grams of both nickel hydrate and flake nickel in approximately 265 alternate layers of each.

The cell is put on three cycles of charge and discharge at room temperature, charging for 15 hr. at 300 mil-amperes and discharging at 200 mil-amperes down to a terminal voltage of 0.9, noting the capacity in mil-ampere hours in each case. The available capacity will usually increase after each cycle; this is no doubt due to increased penetrability of the active mass by the electrolyte, thereby rendering more of it active. The first three runs are followed by ten cycles of charge and discharge, the cell being kept at a temperature of about 54.5 deg. C.; it is discharged to zero voltage in each instance.

The operation of the cell at such a temperature, which is rarely attained in practice, is thought to hasten its deterioration and multiply the severity of the service it will ordinarily be put to under commercial conditions. At higher temperatures, moreover, tests show that both the nickel hydrate and iron have a low effective input on charge, the former exhibiting this phenomenon more decidedly than the latter; obviously, this would result in a lower available capacity. As a matter of fact, however, four subsequent runs similar to and at the same temperature as the first three generally show the cell to have increased in capacity. Such a cell must show at least 1100 mil-ampere hours before the active material is accepted.

For testing the activity of the iron approximately 5 grams are placed in one of the standard pockets and mounted in a test cell. For the first three runs it is charged for 15 hr. at about 0.4 amp. and discharged at 0.3 amp. down to 1.0 volt, noting the capacity in each instance. On the next three runs it is charged at 0.4 amp. and discharged at about twice the former rate down to 0.5 volt, noting capacities

at both 1.0 and 0.5 volts. This is generally followed by two cycles of charge and discharge at same rates as employed for the first three runs, noting the available capacity at both 1.0 and 0.5 volt. A procedure of this character will demonstrate the desirability of the iron. A pocket containing 8 grams of acceptable iron will show better than 1900 mil-ampere hours discharged to 1.0 volt.

An analysis of the terminal voltage of the battery discharging at its normal rate, as typified by the employment of an auxiliary electrode, shows that the potential of the negative plates, or those originally containing iron as active material, is practically constant. This is indicative of the fact that the iron, in addition to being present in greater equivalent amounts, is more active electrochemically than the nickel hydrate, no doubt due to its greater porosity and consequent greater accessibility to the ions of the electrolyte.

This is further substantiated by the fact that the curve representing the difference of potential on discharge between the positive plate, or that originally containing the nickelous hydrate as active material, and the auxiliary electrode has the same general shape as the curve showing the terminal voltage on discharge at normal temperatures. The available capacity of the battery is limited by the behavior of the positive plates on charge and discharge.

Furthermore, owing to the material composing the positive plates having a small electrical conductivity as compared with that composing the negative plates, very thin flakes of metallic nickel are incorporated with the nickelous hydrate in alternate layers in the tubes, pressure being applied after each separate addition to insure more intimate contact between the active material and the walls of the tube; such a process increases the conductivity of the mass as a whole. Obviously, a decrease in electrical resistance cannot be secured by this means except at a sacrifice of the porosity of the active material and consequent accessibility of the electrolyte ions to the interior of the mass.

Schenley Park, Pittsburgh, Pa.

Synopsis of Recent Chemical and Metallurgical Literature

Conveyor Belts

Testing of Conveyor Belts.—From an extended paper on conveyor belts for metallurgical plants, published by A. ROBERTSON and A. MCARTHUR JOHNSTON in the *Journal of the South African Institution of Engineers*, we take the following excerpt relating to methods of testing conveyor belts. The authors advocate the practice of such tests in order to raise the standard of materials used, and as a protection against poor material and excessive charges.

Balata Belts

Balata belts are tested by determining the strength of the warp and filler of the canvas, and by ascertaining the frictioning or adhesion between adjoining plies or layers. In belting the main strength must lie in the warp, though that of the filler should be but little inferior. This strength is found by breaking in the tension machine a section of the belt one inch in width. Care must be taken in cutting this that no thread in the line of the pull be broken before the test.

(1) *Strength of Cotton Duck.*—When for some reason only one ply can be obtained for this test it is advisable to cut a section just over an inch, and detach therefrom single strands until the exact inch is got.

The grips also must bear evenly over a surface, so as to avoid pinching the belt in one place; this may be partly avoided by making the gripped portion larger than an inch—say one and a half inches, with a taper to one inch. The tested portion should be, over the inch section, at least three inches in length.

A specification for the cotton duck used in this belting should note:

- (a) The weight of duck used (ounces per linear yard).
- (b) The number of yarns per inch, both for warp and for filler.
- (c) The tensile strength of the warp and of the filler.
- (d) The amount of stretch in the belt.
- (e) The number of plies in the belt.

To illustrate the variation that exist among this class of belting, the samples being submitted for one particular duty, I may quote the following results:—

Samples tested lengthways of belt (warp). Tensile Strength of Total Belt, one inch in width.

	Number of Ply
(a) 2,806 lb.	8
(b) 3,180 lb.	8
(c) 3,168 lb.	8
(d) 3,564 lb.	6
(e) 3,600 lb.	4
(f) 3,916 lb.	8
(g) 3,136 lb.	8
(h) 1,420 lb.	6

If we neglect the last one as being an inferior lot, we still find a variation amounting to over half a ton per inch in the breaking strain of the different duck used; this means an additional load capacity of 15 tons on a 30 in. belt.

The tensile strength of the filler in certain belts examined shows proportionately even greater differences.

Samples tested, one inch in width.

	Number of Ply
(a) 900 lb.	6
(b) 1,440 lb.	8
(c) 2,288 lb.	10
(d) 1,980 lb.	8
(e) 1,684 lb.	8
(f) 1,584 lb.	8
(g) 1,232 lb.	8

The difference of a breaking strain of 750 lb. per one inch section in the filler of two eight-ply belts is surely worthy of consideration when placing an order.

It is to be noted that the strength of the warp is greater than the filler, and agents should note in submitting samples for test that these be at least 10 to 12 inches in length and about 3 to 4 inches in width, except when the strength of both warp and filler is required, in which case the section submitted should be 10 inches square.

(2) The *adhesion* between adjacent plies of duck is determined by maintaining a steady pull in separating these. A section of the belt one inch in width is taken, and one, or even two or three, of the plies is separated by hand from the remainder for a length of two inches, and the two ends caught in the clamps of the machine shown in Fig. 1 (testing machine). A steady pull is applied by turning the wheel, the rate of turning being regulated so that the jaws may move apart two inches per minute.

The spring balance registers the resistance set up and indicates the effectiveness of the Balata frictioning. The adhesiveness depends on the quality and quantity of the Balata used and the success of the operation known as frictioning.

The Pennsylvania Railroad Company require that the frictioning of their air brake hose be such as to support a pull of 25 lb. while separating at approximately the above rate. Many air hoses on our market scarcely maintain a 11-lb. pull when separating contiguous plies.

FIG. 1—TESTING OF CONVEYOR BELTS

A specification for Balata belts might well demand a friction test of at least 20 lbs. This figure is not often reached here, but if demanded it could easily be got, and would form some guarantee that the belt plies would not readily come asunder.

The following results from a series of tests show actual figures on samples of Balata belt at present in this market:—

Friction Tests

	Lbs.
(1)	21 1/2
(2)	21
(3)	24
(4)	18 1/2
(5)	17
(6)	16 1/2
(7)	15
(8)	14
(9)	13
(10)	12
(11)	11
(12)	5

(3) The *stretch* in the belt is not often determined in the testing laboratory, though, given suitable apparatus, this could be easily done. It is always advisable to test the belt as a whole and not over an inch section.

Rubber Conveyor Belts.

Similar tests are made on rubber conveyor belts, with, of course, the additional testing and analysis of the rubber.

(1) *Canvas Strength*.—Owing to the greater cost of rubber belting, firms are not keen on supplying test lengths of 9 to 12 inches, and as a rule tests of the cotton duck are made on the transverse section. One sample of a very good belt submitted here gave the same tensile strength longitudinally as transversely, but this result would not always be found.

The following are the records of the *total strength* of the cotton duck of seven belts recently examined here:—

	Lbs.
A. Tensile strength on 1 in. transverse section (6 ply)	902
B. Tensile strength on 1 in. transverse section (6 ply)	858
C. Tensile strength on 1 in. transverse section (6 ply)	924
D. Tensile strength on 1 in. transverse section (6 ply)	825
E. Tensile strength on 1 in. transverse section (6 ply)	1,050
F. Tensile strength on 1 in. transverse section (6 ply)	990
G. Tensile strength on 1 in. transverse section (6 ply)	1,350

The *friction tests* on these same seven samples showed that none of them were exceptionally good, while one was exceedingly bad, and three poor. The tests were made on a one inch transverse section.

	Lbs.
H. Friction test between cotton duck layers	10
I. Friction test between cotton duck layers	14 1/2
J. Friction test between cotton duck layers	14
K. Friction test between cotton duck layers	15
L. Friction test between cotton duck layers	8 1/2
M. Friction test between cotton duck layers	9
N. Friction test between cotton duck layers	6

As these results were obtained from belts which are reckoned the best on our market, it would seem that neither the cotton duck used nor the frictioning are as strong in rubber conveyor belts as in Balata belts.

(2) *Rubber layer*.—The value of the rubber layer depends entirely on the quality of the rubber used, on

the vulcanizing it has received, and on its age. One has to handle rubber constantly to realize the depreciation that takes place in this climate, and more especially with the quality of the rubber used for this class of work. It is in my opinion essential in buying a belt to stipulate that it has been but recently imported. Not only does the rubber deteriorate, but the frictioning material used to cement it to the duck loses its adhesive properties.

Two belts which were tested here showed that the rubber layer in each case lost its elasticity to a not inconsiderable extent after a lapse of six months.

Thickness of layer, 3/16 in.

Elongation of a section 1 in. wide and measuring 3 in. between the grips, before breaking.

Q	11 1/2	18 1/2	18 1/2
R	11 1/2	18 1/2	18 1/2

The following results were obtained from seven samples of rubber conveyor belts:

	Incombustible Matter in Rubber, per Cent	Stretch of 3-In. Test Piece, Inches	Friction Test Between Rubber Layers, Lbs.
Q	18.50	1 1/2	12
R	16.05	1 1/2	3
S	42.00	10	6 1/2
T	65.10	5	14
U	37.07	8	9
V	44.04	8	15
W	59.34	8	
X	39.00	8	

Sample W.—The rubber layer in this sample refused to be detached from the canvas layer. As soon as a grip could be obtained and a moderate pull exerted, the rubber tore showing both the poorness of the quality and the effect of climatic conditions.

The elasticity or stretch in the rubber layer is obtained by gripping a section 1 in. wide in the machine used for the friction test, with a distance of 3 in. between grips. The total elongation before breaking or tearing is thus obtained, as is also the tensile strength of the rubber. The following may be quoted as characteristic tensile strengths of a 1-in. section of the rubber layer of belts in good or fairly good condition and ready for the market here:

	Stretch of Rubber (3 In. Between Grips), In.	Tensile Strength, Lbs.
Q	10	8 1/2
R	7	6 1/2
S	12	1 1/2
T	5	12
U	9 1/2	10 1/2
V	8	10
W	8	240

It would be recommended, therefore, that a specification should demand:

(a) That the incombustible matter in the rubber layer be under 50% by weight.

(b) That a section of the rubber layer 1 in. in diameter shall stretch to at least three times its own length before breaking (3 in. to 9 in.).

(c) That the frictioning between any two contiguous layers, rubber and canvas or canvas and canvas, be at least 15 lb.

It is probable that in time these demands could be made more stringent.

Plastic Flow

Laws of Plastic Flow.—Information on plastic flow is important to many industries. The Bureau of Standards has recently conducted investigations on the laws

of plastic flow and published the results as Scientific Paper No. 278. The author of the paper is EUGENE C. BINGHAM. The property of plasticity, like ductility or malleability, is not at present strictly definable, although the term is much more familiar than the strictly defined terms "viscosity" and "fluidity."

In the study of plastic flow it has already been shown that most homogeneous solids will flow somewhat after the manner of liquids, if subjected to sufficient pressure. Copper, steel, lead, ice, menthol, glass, and asphalt fall in this class in so far as they may be regarded as homogeneous solids. But ordinarily plastic substances are not homogeneous solids, but suspensions of finely divided solids in fluids, such as paint in oil, lime in water, and especially clay in water. Numerous papers have been devoted to the explanation of this latter type of plasticity.

Since glass and other similar bodies are often regarded not as solids but as very viscous liquids, the demarcation of viscous flow from plastic flow has not been sharply made. In fact, attempts have been made to give numerical values to the viscosity of ice, menthol, glass, and pitch, and Tammann defines plasticity in a perfectly definite manner as the reciprocal of viscosity—in other words, plasticity and fluidity are synonymous.

Unfortunately, for the sake of simplicity, this definition is clearly untenable. If any finely divided solid, such as clay, be suspended in a liquid, the fluidity is lowered rapidly and in a perfectly linear manner, so that at a comparatively low concentration of clay the fluidity, as measured in the ordinary viscometer, approaches zero. Thus Durham and Bingham found that a certain clay suspended in water gave a zero fluidity when the volume percentage had reached 6.95 (14.6 per cent by weight), this being independent of the temperature. This concentration apparently serves to sharply demarcate plastic from viscous flow. Suspensions more dilute than this critical concentration are subject to viscous flow, while those containing more solid in suspension are plastic.

The experiments of Bingham and Durham support the definition of Maxwell that a plastic body is one in which the form of the body is found to be permanently altered when the stress exceeds a certain value. However, the laws of plastic flow must be known before a rational basis can be obtained for the quantitative measurement of plasticity. The work of the bureau, which was done chiefly on English china clay, is summarized as follows:

The various types of viscous and plastic flow have been considered theoretically. According to the circumstances of the flow the viscosities may be additive, the fluidities may be additive, or slipping or seepage may enter in to affect the character of the flow. The possible separation of the components of a mixture by means of flow has been considered. It has been shown that in a suspension of solid particles in a liquid there must be a dissipation of energy when the solid particles collide, as they must collide if the layers of the suspension move over each other. This dissipation of energy follows the laws of ordinary friction and not the laws of viscosity.

Measurements have been made upon the flow of clay suspensions of different concentrations through capillaries of varying dimensions and at two temperatures.

It is shown that plastic flow can be sharply differentiated from viscous flow by the "friction" necessary to start plastic flow. The friction is a linear function of the volume concentration. It is also affected by the presence of alkalis or acids, but it is independent of the length or diameter of the capillary as well as the temperature of the medium.

For medium pressure the rate of efflux is given by the formula

$$v = K(P - f),$$

where P is the pressure, f is the friction, and K is an arbitrary constant. The experiments indicate that at low pressure seepage takes place causing a perceptible change in the concentration, and that at high pressures there is slipping which under certain circumstances may cause a sudden increase in the rate of flow.

The fluidity becomes zero at the concentration of solid where the plastic flow begins; that is, where the friction begins to have a positive value. This concentration, where the particles are able to form a bridge across the capillary space, is reached long before the concentration corresponds to close packing of the solid particles. For very fine-grained material the range between the concentration giving zero fluidity and the concentration corresponding to close packing will be much greater than in coarse-grained material.

The "mobility" of suspensions has been defined and calculated. The mobility decreases very rapidly from its maximum value in the concentration which has zero fluidity to a value not far from zero in the mixture which corresponds to close packing of the solid particles. The mobility increases with the fluidity of the medium, but is also greatly affected by the presence of alkalis or acids.

Recent Chemical and Metallurgical Patents

Iron and Steel

Accurate Determination of Critical Point During Annealing.—An apparatus for accurately determining the critical point during the annealing operation, and thus affording a more accurate control of the grain size and other properties of iron and steel, is patented by ROY B. FEHR of State College, Pa. The method consists in magnetizing the work under treatment and noting any quick change in the magnetization by a millivoltmeter. When iron or steel reaches the critical point it is no longer magnetic, and thus this point can be determined accurately and need not be estimated or a thermo-couple with its inherent temperature lag need not be depended on, which give varying results in heat treatment.

The apparatus used is shown in Fig. 1. An ingot P is placed in an electrically heated resistance furnace 4. The furnace here shown is heated by a core of nichrome ribbon 3 wound around refractory material. An iron yoke 6 is connected with the ingot, and the yoke is magnetized by the coil connected with resistance 13. A millivoltmeter 10, connected to copper coil 11, serves to indicate the critical point.

In operating, to find the critical point of the heat curve, the exciting current is adjusted by the rheostat 13 until the ammeter reading is of a proper value to produce a flux of suitable density in the magnetic circuit. The switch 12 is then closed and the reversing switch 9 is opened; the momentary large deflection of the millivoltmeter is then read. This reading is proportional to the change in magnetic flux from, say, plus 14,000 units with the magnetizing current to a "residual" flux of, say, plus 7000 units with no magnetizing current. Switch 9 is then closed in the opposite direction, and a reading is obtained corresponding to a change in flux from plus 7000 to minus 14,000 units. These operations are repeated at regular intervals during the heating process, and thus there may be obtained two sets of observations, one set for breaking the circuit and the other for making the circuit. One set would be sufficient, but the other set gives a reliable

check on the work. When the readings in either set suddenly begin to increase or decrease (according to whether the magnetic induction is above or below the "knee" of the saturation curve of steel) I have a positive indication that the metal in the hottest part of the furnace is becoming non-magnetic and ready for heat treatment. (1,188,430, June 27, 1916.)

Operation of Reverberatory Iron-Melting Furnaces.—In melting iron for foundry use in reverberatory furnaces, a uniform temperature from day to day is very

FIG. 1—MAGNETIC CRITICAL POINT APPARATUS

desirable. In operating these furnaces in natural draft, difficulty is experienced in obtaining uniform heat due to changing atmospheric conditions. In order to obviate this difficulty JOHN A. SWINDELL of Pittsburgh, Pa., proposes in a recent patent, to operate on a natural draft at the beginning, and when the iron reaches its full melted condition, the ash pit doors are closed and forced draft put on. In this manner uniform heats are claimed to result. To prevent the formation of clinker at the grate, and also to relieve the cutting action on the furnace lining, due to the forced draft, steam may be introduced underneath the grate. (1,188,111, June 20, 1916.)

Production of Ferromanganese.—An electric furnace process for producing ferromanganese from waste clinker or cinder from zinc furnaces, and also recovering the zinc, is patented by HARRY SCHAGRIN of South Bethlehem, Pa. The furnace in which the process may be carried out is shown in Figs. 2 and 3.

The waste clinker or cinder from zinc smelters using franklinite or willemite ores, containing 15 to 22 per cent MnO, 28 to 56 per cent FeO, 20 to 30 per cent SiO₂, 8 per cent C, 6 per cent Al₂O₃, 10 per cent CaO, and about 4 to 5 per cent ZnO, is crushed to a suitable size, mixed with 25 per cent by weight of waste coal dust, and a quantity of limestone flux. The charge is placed in hopper 6, and fed by the screw conveyor to the furnace stack. When a sufficient amount of the charge has accumulated around the electrodes, the current is turned on and the temperature brought up to 1500 deg. C. while charging continues. The charge melts, forming the molten pool 20, when the iron and manganese settle down and the slag rises to the top.

The zinc in the charge is volatilized and is drawn off by suction through openings 21 to chamber 23, where it settles. Any zinc passing up beyond the pipes is caught and condensed by the downcoming charge, which is cool at the top and returned to the fusion zone. A reducing atmosphere is maintained in the furnace, and the temperature is not allowed to rise much over 1500 deg. C. It is claimed that the process avoids serious loss of manganese, and works well on low manganese material. (1,190,679, July 11, 1916.)

Production of Silicospiegel.—A modification of the above process as adapted to the production of silicospiegel is described in another patent of HARRY SCHAGRIN. In this case the charge is substantially the same, but the temperature is raised to 1800 to 2000 deg. C. The zinc is volatilized and collected as before, and silicon is reduced along with the iron and manganese, producing on the hearth an alloy containing from 10 to 15 per cent silicon, 10 to 20 per cent manganese, 15 per cent aluminium, and 60 to 70 per cent iron. (1,190,678, July 11, 1916.)

Electrochemistry

Manufacture of Aluminous Abrasives.—A process of making aluminous abrasives which aims to avoid the intermittent running of the furnace and to make the process more continuous is patented by THOMAS B. ALLEN, of Toronto, Can. The patent is assigned to the

FIG. 2—END VIEW OF FERROMANGANESE FURNACE

General Abrasive Company, of Niagara Falls, N. Y. The process consists in heating a mixture of bauxite and coke in an electric furnace, and tapping separately the resulting abrasive and by-product such as ferro-silicon. The by-product is formed as a result of the reduction of iron, silicon and titanium oxides contained in the bauxite. In Fig. 4 is shown a furnace in which the process may be carried on. A is a brick foundation, B is a lining made of a mixture of coke and tar, F is a tap hole for abrasive, G is a tap hole for ferro-silicon. Carbon electrodes are shown at C. Polyphase current

FIG. 3—LONGITUDINAL VIEW OF FERROMANGANESE FURNACE

is preferably used with the necessary number of electrodes.

The charge is made up of 100 parts by weight of calcined bauxite, to nine parts of coke. These are both ground fine and intimately mixed. The mixture is charged and heated in the furnace until 7000 to 8000 lb. is melted and reduction has taken place, which can be judged by the appearance of the molten mass. As soon as reduction is complete and sufficient time elapsed for the settling of the ferrosilicon, the abrasive in molten form is removed by means of the tap hole *F* and

FIG. 4—ALUMINOUS ABRASIVES FURNACE

cast into ingots of a size determined by the quality desired in the abrasive produced. After its removal the ferrosilicon is tapped out by means of the tap hole *G*. The process is then repeated before the furnace cools. The abrasive after cooling is crushed up into suitably sized grains and is then in shape to be used for abrasive purposes. (1,187,225 June 13, 1916.)

Electric Furnace.—An electric furnace which is rotatable horizontally about a vertical axis and which may also be tilted for pouring the charge is patented by PETER EYERMANN, of Witkowitz, Austria-Hungary. A sectional view of the furnace is shown in Fig. 5. The crucible 1, is made of any suitable refractory material and is supported on a frame or cradle 5, by means of annular ball bearings 2, and an upright pivoted bearing 24 at the axis of rotation of the crucible. The crucible is rotated by means of a worm 10, which is driven by an electric motor. The frame and crucible may be tipped for pouring by rocking on the base 27 by means of hydraulic mechanism, as shown at 23. The electrodes 8, extend through the roof as shown. They may vary in number and are so arranged on the roof that the center line of the group, represented by the line 19-19, will be eccentric with regard to the axis of rotation of the crucible, represented by the line 3-3, so that when the crucible is rotated on its axis, each of the electrodes describes a different path, thus subjecting the various parts of the metal to the action of the current. This feature is claimed to necessitate only a small number of electrodes. (1,189,356, July 4, 1916.)

Electrolytic Cell for Magnesium.—A method of production of magnesium or other alkali metals by electrolysis so that the metal collects in considerable amounts is described in a patent of CHRISTIAN DANTSIGEN of Scotia, N. Y., which is assigned to the General Electric Company. The feature of the cell is a cathode which will alloy slowly with the magnesium. The cell is made of magnesite brick, and a fused electrolyte of potassium chloride and magnesium chloride in molecular proportions, to which may be added 2 or 3 per cent of calcium

fluoride is used. Anodes are of carbon, and cathodes are of sherardized iron, copper-coated iron or tin-coated iron. Any of these will alloy slowly with the magnesium and produce large masses of magnesium at the cathode. The molten metal wets the surface of the zinc-iron alloy, and hence remains attached. An advantage is gained if several cathodes are used in one cell as a more effectual collection of the magnesium takes place. The

FIG. 5—REVOLVING ELECTRIC FURNACE

amount of zinc which will alloy with the magnesium is small, and may be neglected for any of the known commercial uses of metallic magnesium. (1,190,122, July 4, 1916.)

Separation of Neon from Other Gases of the Atmosphere.—The production of liquid air in a large scale has made possible the production of large amounts of nitrogen and also made possible the production on a commercial scale of the other gases contained in the atmosphere, such as argon, helium and neon. A process of separating neon from the other gases mixed with it, more particularly helium, is patented by GEORGES CLAUDE of Boulogne-Sur-Seine, France. A tube such as shown in Fig. 6 contains carbon electrodes *g*, and connections *m* and *n* for a vacuum pump and impure

FIG. 6—NEON PURIFYING TUBE

neon respectively. The tube is exhausted to a pressure varying between 0 and 10 mm. of mercury and the gases admitted. An electric discharge is then passed through and the foreign gases are absorbed, leaving the neon in a substantially pure state. The minimum surface area is 1.5 sq. dcm. per ampere. A comparatively large surface area is desirable since the neon is absorbed so much more slowly than the other gases.

The process is particularly applicable when the puri-

fied neon is to be used in a rarified state in the enclosure in which it has been obtained. The neon is extremely permeable to electric discharge and has found application in detectors of Hertzian waves, luminous tubes, etc. The process is of especial interest as it makes it possible to separate neon from helium effectively. (1,191,495, July 18, 1916.)

Alloys

Heat-Resisting Alloy.—A patent has been granted to JOHN C. HENDERSON of Washington, D. C., and assigned by him to the Driver-Harris Wire Company of Harrison, N. J., on the manufacture of cast articles of nichrome. A description of experimental work done on these articles was given in this journal, Vol. XV, page 159, Aug. 1, 1916. The articles are intended to withstand temperatures of from 1000 deg. Fahr. upwards without suffering corrosion, pitting or oxidation. The composition is nickel 60 per cent, iron 26 per cent, chromium 12 per cent, and manganese $1\frac{1}{2}$ per cent. If substantially carbon free (less than 0.4) the alloy can be machined, rolled or forged. The alloy requires a high melting heat, but when once sufficiently melted can be cast in the ordinary manner. Some of the articles mentioned are molds for die casting, valves and valve seats for internal combustion engines, crucibles, outer casings for crucibles, linings for molds and crucibles, annealing boxes, case-hardening or carburizing boxes, and other apparatus. The manganese is not essential but is merely the remnant of manganese from the raw materials used.

When subjected to oxidizing temperatures, a slight film of oxide forms on the surface of the article, which is strong and durable, and resistant to sulphuric and hydrochloric acids and alkalis. This oxide is non-flaking and adheres strongly to the mass. (1,190,652, July 11, 1916.)

Measuring Water with a Weir Meter*

BY E. G. BAILEY

A V-notch or rectangular weir offers many advantages for measuring water at or near atmospheric pressure. The flow curve is such that greater accuracy is readily obtained over a wider range in rate of flow than with the Venturi or Pitot tubes. From an accurate knowledge of the flow curve for any given shape of weir notch, it is possible to use the level of the water above the notch to continuously record the rate of flow and integrate it so that the total may be read from time to time. The nature of the flow curve of a V-notch weir as shown in Fig. 1 brings out clearly the point that at low rates of flow there is proportionately a great deal of head, or power, to operate any float-driven mechanism. The converse is true at the higher heads where a very slight change in head means a much greater change in rate of flow.

The accuracy of the V-notch has never been questioned but the points of primary importance are to accurately measure the head and to be sure that this measurement is referred back to the true zero of the notch. These points are difficult enough when using hook gages with micrometer screws in a hydraulic engineering laboratory, and even more so when continuous recording and integrating mechanism is used to measure the rate and total flow.

The zero level can be readily obtained in test or calibration work if a permanent hook gage point is

riveted to the weir plate as shown in Fig. 2. This can be accurately located in the machine shop and is absolutely correct by construction.

It is always preferable to have chart records on uniformly graduated charts and in order to use the best form of integrating devices it is essential to have a motion directly proportional to the rate of flow instead of proportional to the head.

There are many ways in which this may be accomplished with more or less accuracy, but the motor with the simplest mechanical construction always gives the best satisfaction and continued accuracy over a long period of time.

The mechanism used in this apparatus operates on the buoyancy principle, as shown in Fig. 2. The displacing members are exactly balanced and weighted so that they are heavier than water and do not act as floats. If they were of equal and uniform cross sec-

FIG. 1—FLOW CURVE

tional area the rising of the water level would produce no motion but would merely cause them to become lighter on their knife edge supports by an amount equal to the weight of water displaced. But by properly shaping these spun copper displacing members a powerful motion that is directly proportional to the actual flow is obtained directly from the main shaft itself.

Thus when the rate of flow is 25 per cent of the maximum capacity of the meter, the motion given to the pen is 25 per cent of the total motion. At this point the level of the water has increased to 57 per cent of the total range in head.

The motion of the displacing members, and also the recorder pen, has not been relatively as much as the change in head, but it is directly proportional to the rate of flow. The total motion of each displacing member is, of course, less than the total change in water level. The maximum head is 10 in. and the corresponding motion of the displacing member is 4 in.

The characteristic of the flow curve of a V-notch weir is the basis for the often repeated argument of its great accuracy at the low rates of flow. But upon closer analysis it is found that this argument is a boomerang when considered in relation to the higher rates of flow, unless the recording mechanism is properly designed. An error of a few hundredths of an inch in a hook gage or straight float that rises directly with the water level may mean as much as 5 per cent error in the flow of reading at the higher rates.

The design of this weir meter entirely obviates the

*A paper read before the June meeting of the Ohio Society of Mechanical, Electrical and Steam Engineers at Cleveland. Slightly abstracted. The author is president of the Bailey Meter Company of Boston, Mass.

FIG. 2—PRINCIPLE OF METER

possibility of such an error, for the relative position of the two displacing members is made right by construction, and no changes can possibly take place to alter it. The pen and integrator can be set to their true zero so long as the water level is within $\frac{1}{2}$ in. of the bottom of the notch, and there will be no error at the higher readings.

The working arrangement of these displacing members is shown in Fig. 3. The beam which carries the displacing members on monel metal knife edges is fastened to a shaft supported on monel metal knife edges. The end of this shaft extends through a pressure-tight bearing and carries the recorder pen and integrator driving directly on its outer end.

The question of integrating the flow of any fluid brings up many problems that have been more or less troublesome on other types of meters as well as of the weir type. Principal among these are imperfect drive due to vibration and the wearing smooth of the driving disc.

A detail of the integrator which has been found very satisfactory is as follows: In this the disc is driven by the same clock movement which drives a chart; the disc making two revolutions per hour. The counter is suspended from a knife edge bearing on the clock frame and is moved across the disc by an arm extending from the main shaft which also carries the recorder pen. The follower wheel which is in contact with the clock-driven disc bears in the center for zero flow and is moved outward to a radius of $3\frac{1}{2}$ in. at maximum rate of flow. This follower wheel is provided with a large number of rollers on its circumference which practi-

cally eliminate friction as it is moved across the disc and also prevents wearing the disc smooth, so that continued accuracy is obtained over an indefinite period of time without attention. The axis of the follower wheel is mounted slightly inclined from the perpendicular to the clock-driven disc so that the follower wheel bears against its projecting edge instead of its extreme circumference. This gives a greater arc of contact and eliminates error due to slip. This wheel is held against the disc by a flat spring and a small pressure of this part prevents any error due to vibration. This arrangement also simplifies the construction so that spur gears are used to drive the countertrain.

A record of one of these meters when receiving returns from one system which had an electric motor-driven pump that is intermittent in its action due to a float control showed interesting results. The meter calibration test Jan. 28th was made on this meter on this day when the rate of flow was varying from less than 2 per cent to over 90 per cent of the meter's rated capacity, every 8 to 10 minutes. The last calibration test which was made was at a very low rate, it being only 1240 lb. per hour, which is $2\frac{1}{2}$ per cent of the meter capacity. One of these meters agreed within 2.7 per cent of actual weight on the 15-hour tests, and while the other meter shows a larger percentage error yet this is equivalent to only 1 per cent at 35 per cent capacity, and this error would be produced if the follower wheel was only one hundredth of an inch out of its true adjustment, which was found to be the case at the end of this calibration.

A record of the water temperature is also made on the same chart with the rate of flow. This is accomplished by means of a recording thermometer having its bulb located in the flowing water. If temperature record is not desired the full pen motion on a 12-in. chart may be had.

New Design of Automatically Controlled Low-Pressure Valve

The adjoining illustration shows a low-pressure steam valve, electrically operated, requiring 0.5 amp. and 110 volt direct current, which has been developed by the Geissinger Regulator Co., 203 Greenwich Street, New York City. It is used in connection with the automatic "equitherm" controller of temperatures, and has proved to be an economizer of waste steam in large plants. It is used on apparatus requiring low-pressure steam.

The valve opens and shuts under the guidance of an electric thermostat, the lead *C* shown in the illustration connecting the thermostat with the magnet head *B*. The fall of temperature past the critical degree closes the thermostatic circuit, energizes the relay coil in the control cabinet, and closes the valve coil circuit contained in the magnet head *B*.

This attracts the armature of the pilot valve stem in the pilot valve *E*, which on lifting allows high-pressure steam from line *D* to pass through the pilot valve and under the piston contained within the high-pressure cylinder *G*.

A rod connects the piston and the bottom of the low-pressure valve disk, so that when the piston rises the low-pressure valve disk is lifted off its seat, against the low-pressure steam, which is on top of the valve disk.

The low-pressure inlet on top of the valve disk is shown at *A*.

The valve works on the principle of a check valve. It takes pressure and gravity to close it. The high-pressure steam is used as an agent to open the low-pressure valve automatically. There is no waste of the high pressure, as it acts as a heating unit with the

FIG. 3—WORKING ARRANGEMENT OF METER

AUTOMATIC LOW PRESSURE VALVE

low-pressure steam. This type of low-pressure valve makes it possible to utilize exhaust steam. When the supply of low-pressure steam is not enough at a certain time the high-pressure will take care of the difference when necessary. Under ordinary conditions control can be maintained within 1 to 2 deg. Fahr.

Enlarging Photographs Without the Use of a Lens

An interesting American Physical Society paper by Alfred J. Lotka of the General Chemical Company of New York City, is published in the June, 1915, issue of *Physical Review*, describing a new method for enlarging photographs without the use of a lens. This method was developed by the author as the result of an observation of a peculiar distortion presented by the appearance of certain moving objects.

The method consists in moving the negative to be

FIG. 1—DIAGRAM OF APPARATUS

enlarged past a narrow slit source of light, and at the same time moving a sensitive plate under the negative at a speed equal to some constant multiple n of the speed of the negative.

On development of the sensitive plate a positive transparency is obtained, in which all lines of the original negative which were parallel to the slit during the exposure are unaltered, while all lines at right angles to the slit are magnified in the ratio $n : 1$.

This positive is subsequently subjected to a repetition of the process practised on the original negative, but with the motion now at right angles to the lines drawn out n -fold in the first operation. The result of the second operation is a negative geometrically similar to the original, but with the linear dimensions enlarged n times, or the area n^2 , as will be easily understood.

The apparatus employed for carrying out the process has been constructed on exceedingly simple lines, with the use of material readily obtainable on the market. The slit is made with two strips of brass picked from the stock of a wholesale hardware store and having received no other treatment than a cleansing with a brass polish.

The ratio n of the velocities in the apparatus so constructed is 2, and is secured by the simple expedient shown diagrammatically in Fig. 1. In this drawing the original negative is represented at A, the sensitive plate at B, and the slit at S. The carrier C, on which the plate B rests, has attached to it at each end a silk thread D, which passes through an eye E, attached (with gummed paper) to the glass plate of the negative (when a celluloid film is used, such film may be attached with gummed tape to a glass plate). The further end of the silk cord D is attached to the end block of the box containing the negative and plate during exposure. The carrier C slides on the bottom of the box, between guides adjusted to fit the sides of the plate.

It will readily be seen that, in accordance with the principle of the single movable pulley, the velocity of the sensitive plate is always double that of the negative.

Any means, such as a hand-pull at P, may be employed to impart uniform motion to the negative. A cylinder containing water through which a fairly snug-fitting perforated piston is drawn makes a good dash-pot to regulate the motion. This and a still simpler and exceedingly compact device for this purpose is a subject of a pending patent application.

The adjustment of the lamp vertically above and in the plane of the slit is effected by looking down at the lamp and its reflection in the glass covering the slit. When the filament, its image and the line of the slit coincide in the line of sight, the filament is in the plane of the slit. It was found that with a slit $6\frac{1}{2}$ in. long good results were obtained with a filament of six or seven coils placed about 1 ft. from the slit.

Among the advantages which the new method presents is uniformity of illumination over the entire field; geometric similarity to the original of the image produced, i.e. absence of distortion such as spherical aberration introduces; compactness and simplicity of apparatus, replacement of lens by a simple slit and hence low cost of the apparatus.

The process necessitates two successive exposures, but this is true also of the ordinary method when a negative is to be prepared from a negative.

The example shown in the accompanying half-tone illustration gives an idea of the working of the process, though it does not represent the best that can be done in the way of definition.

The limiting separation which the apparatus will effect can be figured as follows:

Consider a point right on the edge of the negative. This will begin to be reproduced on the sensitive plate as soon as the negative and plate are in the position

FIG. 2—DIAGRAM OF APPARATUS

shown in Fig. 2a. (The slit is here shown on a greatly enlarged scale.) The same point will continue to be reproduced until negative and sensitive plate are in the position shown in Fig. 2b. It will therefore be drawn out into a line of length $ns - s = (n-1)s$.

FIG. 3 — HALF-TONE COPY OF ORIGINAL PHOTOGRAPH

FIG. 4—COPY OF DISTORTED POSITIVE TRANSPARENCY OBTAINED IN FIRST STEP OF PROCESS

FIG. 5—COPY OF ENLARGEMENT OBTAINED IN SECOND STEP

Now consider two points, a distance d apart in the negative. In the copy they will appear as two lines $(n-1)s$ long and with their centers nd apart. These two lines will just coincide at their ends when

$$nd = (n-1)s,$$

$$d = \frac{n-1}{n}s.$$

This distance

$$d = \frac{n-1}{n}s.$$

between two points on the original negative represents the limit of separation: Two points a distance greater than d apart will be separated, two points nearer together than d will not be separated.

For $n = 2$ as in the apparatus constructed, we have $d = \frac{1}{2}s$.

Thus, for example, a comparatively coarse slit 1/100 in. wide, will still separate points just a little over 1/200 in. apart.

The process and apparatus here described are protected by U. S. Pat. 1,176,384 of March 21, 1916, issued to Alfred J. Lotka.

Personal

Mr. Walter A. Barrows, Jr., of Brainerd, Minn., who for some years has been engaged in iron mining in Minnesota, has been elected president and general manager of the Thomas Iron Co. of Easton, Pa. He succeeds Ralph H. Sweetser, who recently resigned.

Mr. Samuel H. Dolbear, consulting mining engineer, of San Francisco, was in New York a few days during the middle of August. He went from New York to Washington and from there back to San Francisco.

Mr. R. H. Fash, chief chemist of the Chickasha Cotton Oil Co., has been appointed active vice-president of the Fort Worth Laboratories, Fort Worth, Tex.

Mr. E. T. Foote, formerly of the New York office of the Cutler-Hammer Mfg. Co., and at one time in the engineering department at its Milwaukee factory, has recently been put in charge of the Boston office, located in the Columbian Life Building. Mr. Foote's experience in the engineering department and sales engineering work in New York fit him admirably for his new position.

Dr. Milton Hersey of Milton Hersey Co., Ltd., Montreal, Canada, has returned from a trip through the Northwest, where he has been investigating the resources and industrial possibilities of the country for the Canadian Northern and Grand Trunk Pacific Railways. His company has recently opened an office in New York City at 198 Broadway.

Mr. M. H. Kuryla is in charge of erection of the new electrolytic zinc plant of the Judge Mining & Smelting Co., Park City, Utah. In our issue of Aug. 1 it was erroneously stated that Mr. M. H. Atwater was in charge.

Mr. S. G. Lilja, formerly with the Helsenborg Copper Works, Helsenborg, Sweden, is now engineer with Hamilton & Hansell, Stockholm. He has recently been in this country looking over the electric furnace field.

Mr. N. Petinot, formerly with the Titanium Alloy Mfg. Co. of Niagara Falls, N. Y., has opened an office at 200 Fifth Avenue, New York, as electrometallurgical engineer specializing in ferroalloys.

Mr. Wm. Printz, formerly assistant sales manager of the Brown Instrument Co., Philadelphia, Pa., will be in charge of the new Detroit office of the company opened on Sept. 1. The office will be located at 612 and 613 Chamber of Commerce Building.

Prof. M. C. Whitaker, professor of chemical engineering at Columbia University, has been granted leave of absence for the first term of the academic year 1916-1917.

Industrial Notes

The Thwing Instrument Co., Philadelphia Pa., has issued general catalog No. 8, describing Thwing electrical recording pyrometers. Three types of pyrometers are described, viz.: thermoelectric, radiation, and resistance.

The Foxboro Co., Foxboro, Mass., has issued Bulletin No. 104, describing Foxboro indicating and recording thermometers. Four classes of instruments are described, ranging in temperature scales from 60 deg. F. to 900 deg. F.

The Elyria Enameled Products Company, Elyria, Ohio, has erected a new chemical laboratory equipped to carry on a full line of analytical and research work. The company feels that the addition of facilities afforded will enable it to be of larger service to its friends.

Petroleum Output in 1915.—The petroleum output in the United States in 1915 broke all previous records with a production of 281,104,104 barrels. This is nearly a 6 per cent increase over 1914. The average price received at the well was 64 cents per barrel. Oklahoma led in production, with nearly 98,000,000 barrels. California was second with about 86,600,000 barrels. The next largest producer was Texas, with about 25,000,000 barrels.

New Chemical Plant in St. Louis.—The Mineral Refining & Chemical Co., a company formed last January, is constructing a large plant at St. Louis, Mo., for the manufacture of a substitute for white lead and zinc white in paint manufacture. The daily capacity will be 50 tons. Eight wood and stone buildings will comprise the plant. The construction work is being done by the Fruin-Colnon Contracting Co. Jose Harimon, president of the Spanish Bank of Commerce and the Spanish Bank of Cuba, at Havana, is president of the new company.

Pyrometers.—The Brown Instrument Company, Philadelphia, Pa., are now manufacturing indicating and recording pyrometers for ranges from 400 deg. F. to 3000 deg. F. (1600 deg. C.), and also recording thermometers for low temperatures. These will be on exhibit at the coming Exposition of Chemical Industries in New York in September.

C. O. Bartlett & Snow Co., Cleveland, Ohio, has received the contract for equipping the plant of the Cosmopolitan By-Products Co., New York City, with the Cobwell system of garbage reduction.

New Refiner for Paper and Pulp Industry.—The Manitowoc Engineering Works, Manitowoc, Wis., has issued a circular describing the Howard refiner, which has found successful application in paper, pulp, and other industries.

The Cutler-Hammer Mfg. Co., Milwaukee, Wis., has leased new and larger New York City offices on the nineteenth floor of the Hudson Terminal, 50 Church Street, providing nearly double the space previously occupied. Mr. W. C. Stevens is manager of this office.

Aparatos Destiladores de Agua.—Messrs. Eimer and Amend, New York City, have issued a pamphlet in Spanish describing the Barnstead & Stokes water-distilling apparatus.

Cost System for Manufacturers.—The Federal Trade Commission, Washington, D. C., has issued a pamphlet entitled "Fundamentals of a Cost System for Manufacturers." This pamphlet shows briefly the importance of accurate manufacturing costs and the fundamental principles underlying them, and should prove of value to a great many manufacturers who have not gone into detail in the subject of costs.

The Denver Fire Clay Company, Denver, Colo., has issued an attractive booklet, designated Catalog D, describing Case metallurgical furnaces for melting, refining, assaying, tempering, annealing and enameling. Furnaces are described operating on fuel oil, gasoline, gas, coal, coke and wood.

Multiblade Fans.—The Clarage Fan Company, Kalamazoo, Mich., has issued catalog No. 5, describing the Clarage-Kalamazoo multiblade fan for heating or ventilating installations. The catalog includes capacity and dimension tables for facility in determining what size to use.

Trust Laws and Unfair Competition.—The U. S. Commissioner of Corporations, Joseph E. Davies, has just issued a long report on "Trust Laws and Unfair Competition." This report grew out of the preparation of a large amount of material in connection with the antitrust legislation enacted recently, and it was decided by the Secretary of Commerce and the Commissioner of Corporations that the material was of such a character that it ought to be placed in permanent form to be available for publicists, economists, business men and statesmen for reference. This treatise designs to cover in compact form the laws of the various countries of the world pertaining to the prevention or regulation of monopoly by government, and

the prevention of unfair practices of competition. The last chapter is on the activities of trade associations and their relation to laws concerning competition in the United States.

Determination of Aluminium.—The Bureau of Standards has published the results of research work done on the determination of aluminum, as Scientific Paper No. 286. From observations made with a hydrogen electrode and with suitable indicators, the conditions for the quantitative precipitation of aluminium hydroxide by ammonium hydroxide were determined. In practice, the completion of precipitation may be defined by means of methyl red or rosolic acid. The effect of various factors upon the precipitation, washing and ignition of the precipitate was determined. The procedure for obtaining accurate results is also described.

Vanadium Company Sold.—The American Vanadium Company of Pittsburgh, a \$700,000 corporation, formed in 1906 to mine and sell vanadium, has been purchased by a group of Eastern capitalists, and a new company formed to take over and operate the old company. The new company will have a capitalization of \$13,500,000, and will operate under the old name. James J. Flannery of Pittsburgh, president of the old company, will become chairman of the board, and J. J. Replogle, now vice-president and general manager of sales, will be president. The American Vanadium Company controls the largest part of the known vanadium deposits of the world, its use in high-speed steel having given rise to a considerable production.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath, Cathodes Metallizing

211,610, Jan. 21, 1879, Napoleon W. Williames of Philadelphia, Pa., assignor to himself and Wm. W. Keys, of same place.

Relates to bronzing iron railings, etc., for ornamental iron work, enclosures, etc. The iron is first coated with a paraffin varnish, and this coated with plumbago; it is then immersed in a copper-plating solution, such as the sulfate or chlorid, and copper deposited thereon.

215,034, May 6, 1879, Isaac Adams, Jr., of Boston, Mass.

Relates to covering metals with vulcanized rubber. The metal article, if other than copper, is first coated with a thin film of copper; if the metal article is copper, then a thin film of other metal is first applied, such as tin, nickel, iron, etc., and upon this is applied a thin film of copper. Instead of a film of copper, one of silver may be used. Copper and silver have a tendency to unite with the sulfur in the vulcanized rubber, and it is this property which makes these metals useful for this purpose. After the copper film is formed, the rubber is applied and vulcanized to the copper in a mold, or under pressure.

226,873, April 27, 1880, Irwin M. O'Donel of Pittsburgh, Pa., assignor of one-half of his right to William J. Fullerton of same place.

Relates to the formation of molds having non-oxidizable surfaces, for the manufacture of molded glass, etc. A pattern of the article to be molded is made of clay, wax, or other suitable substance, and a coating of

graphite applied to the surface to be imitated. The pattern is then immersed in a solution of platinum, cobalt, or other non-oxidizable metal or alloy, and a deposit thereof produced on the graphite. The mold is then removed to another vat containing a solution of a cheaper metal, and a deposit of sufficient thickness applied to strengthen it. The deposited shell is then removed and placed in a suitable mold, and a sufficient amount of iron is then cast to or upon it to strengthen and preserve it. It is then finished on its edges, etc., and is ready for use. Metal molds which need to be repaired may be electroplated with a non-oxidizable metal to reduce them to the desired size. The alloy preferred is composed either of iridium or platinum and copper, in the proportion of about one-half each.

227,370, May 11, 1880, Albon Man of Brooklyn, N. Y.

Relates to uniting or framing pieces of glass, china, porcelain, crockery, stoneware, etc. The materials may be first fire-gilded, silvered, or platinized on the parts to be metalized; or the materials may have a coating of lead, zinc, or other metal, or oxids of metals or their salts, applied in a hot state, to the surfaces to be coated, to render it conductive. Or an amalgam of mercury and tin or other metal may be applied; or the surfaces silvered by the precipitation of metallic silver by the mirror silvering process. The coated pieces are then assembled and electroplated, thereby uniting or joining into a unitary structure. Or the several separate pieces may be copper-plated, and then soldered together. The method is said to be useful in securing several glass or porcelain pieces together, or to metal, such as the parts of philosophical apparatus, incandescent lamps, ornaments, etc.

240,615, April 26, 1881, Frederick S. Shirley of New Bedford, Mass.

Relates to the manufacture of molds for making pressed glass, etc. A suitable model of the article to be made with the desired ornamentation is coated with graphite and electroplated with a heavy deposit of copper or other suitable metal or alloy. The deposit is then cut in suitable sections to make a sectional mold, studs or lugs being first secured to the backs of the deposited metal to serve as anchors in reinforcing metal later cast against the backs of the mold sections.

299,055, May 20, 1884, Thomas W. Collins of New York, N. Y., assignor of one-half to Alfred H. Smith & Co., of same place.

Relates to securing diamonds in the edges of cutting tools, by depositing copper in the recess in the tool in which the diamond is placed. The diamond is first coated with copper as follows: It is dipped in a solution of phosphorus in bisulfid of carbon, then dried in the atmosphere. It is then dipped in silver nitrate solution until it becomes black. It is then washed, and if further metallic coat is desired, it may be dipped in chlorid of gold solution. It is then copper-plated. Instead of the above, after receiving the phosphorus coating, the diamond is placed in a solution of nitrate of mercury, and thereafter copper-plated. The copper-plated diamond is then placed in its dovetail shaped recess, and copper deposited in the space around the diamond to secure it in place. Other abrasives, such as corundum, emery, etc., may be secured in this manner.

321,711, July 7, 1885, William A. Gay of Newark, N. J.

Relates to the deposition of metal upon the surface of earthenware and the like, and consists in mixing finely-powdered clay, coke, etc., with sugar solution, tar, or other carbonaceous material, in the approximate proportions of 14 lb. of syrup or tar to about 45 to 50 lb. of the base or powder. The unsized baked earthenware

is covered at the desired places with the above mixture, and the whole submitted to pressure under moderate heat until the mass has firmly adhered to the article. The coated articles are then placed in crucibles, the spaces being filled with sand to exclude air, and the crucibles covered. They are then heated to a dull red heat for from one to two hours, and then allowed to cool. The carbonized surfaces are then cleaned free from sand, and are ready to receive the metallic deposit.

339,431, April 6, 1886, William J. Ladd of New York, N. Y.

Relates to an apparatus for connecting electrotype molds to conductors, and consists of a metallic hanger having mold-suspending hooks which are insulated. Contact with the metallic hanger and mold is made by an independently removable metallic contact piece capable of being secured to the hanger and which presses tightly against the conducting surface of the mold. The circuit may be broken at any time by removing the contact piece, without removing the mold from the electrolyte. The contact piece may be provided with a clock dial and adjustable hands to indicate the time the circuit should be broken, etc.

344,397, June 29, 1886, Robert F. Nenninger of Newark, N. J.

Relates to the manufacture of an electroplated fabric consisting of flexible material such as paper-pulp formed into sheets and dried. The fabric is then made waterproof by soaking in linseed oil, etc., and drying. The waterproof fabric is then stitched through at many points on both sides over each entire surface with bare copper wire, the wire extending for short lengths at each stitch on each surface of the fabric. One or both surfaces of the fabric are then coated with graphite, and the fabric immersed in the electrolyte. The metallic deposit anchors itself to the copper wires and spreads over the entire fabric. When completed, the plated fabric may be used for floor or wall covering, lining refrigerators, etc.

347,195, Aug. 10, 1886, David S. Plumb of Newark, N. J.

Relates to ornamenting glassware and the like, such as pitchers, etc., and consists in applying to the surface of the glass a continuous network or openwork of wax, glass cement, paint, etc., and producing the design in the wax, etc. A coating of bronze powder or graphite is now applied to the ornamented wax, and then electroplated with gold, silver, etc. The electroplate may be engraved if desired.

360,672, April 5, 1887, Otto S. Fertig of New York, N. Y.

Relates to hangers for suspending electrotype molds in an electrolyte, and refers to an earlier patent, number 151,892. The hanger is provided with two insulated metallic hooks by which the mold case is suspended, to prevent it from tilting sideways, and a metallic strip to make electric contact with the face of the mold.

362,927, May 17, 1887, Edward A. Blake of Chicago, Ill.

Relates to an apparatus for coating electrotype matrices with graphite. The matrix is placed upon a support in a suitable box having an outlet at the bottom, and through the top of which is directed a blast of air carrying graphite; the graphite is blown directly upon the matrix, into all the depressions, and provides an even and smooth coat of graphite over its entire surface. The excess of graphite is blown away and collects in the lower part of the box, from which it passes through the outlet therein and through a conduit up to a hopper which communicates with a blower supplying the blast of air to the matrix.

Metallurgical and Chemical Engineering

Chemists in Combination

Two great chemical societies meet in New York during the week of September 25 to 30, when the chemical exposition takes place: the American Chemical and the American Electrochemical Societies. That the major organizations should meet at the same time is reasonable and wise, provided the idea is not carried too far. If the Chemical Engineers and the Society of Chemical Industry were also to foregather on the same days there might be a little overlapping.

The number of chemical bodies is a sign of activity, and they spur one another on to avoid the ruts and grooves of dullness. It is very easy for a learned society to grow obese and heavy, to save its offices as rewards for age and prosperity among the incumbents and to meet for the achievement of dignity and admiration. It is pleasant to sit, fat-headed, in big chairs, to pass resolutions in praise of science and the learned and distinguished body of savants who grace the occasion by their inspiring presence—and let it go at that. Most of us are capable of drifting into just such complacency—if nobody bothers us and everything comes our way and there isn't anybody else to do better. But when learned societies multiply—within reason, of course—there is less likelihood of the substitution of mutual admiration for work. One or two of them is bound to get busy, and with that the others also see that there is something to do.

We have in mind a certain society that had its origin and was located far away from here, with a name as imposing as that of the Sultan of Turkey and a charter as broad as that of the Manhattan Company, that for years and years did not contribute a single thing of real value to the public welfare. It had strong men and good men among its members, but the society did not do anything. It just lived along, blissfully content, assured of its social standing, and it served the purpose of its organization for public welfare by posing as the repository of transcendent wisdom. Suddenly a new condition arose and the service which it was supposed to render was called for. Then came trouble; pose the honorable body had; pose and poise, but it could not work; it was not set up to work. All of a sudden some technical men were drummed up apparently from nowhere at all, and the plain fellows, without honors and decorations, turned the trick and saved the day.

Now there is no present danger that such a situation will arise among our chemical societies. And yet, safety lies not so much in numbers as in the absence of vanity. Self-sufficiency is the killing thing. As soon as all the societies regard themselves as Perfect and Final Repositories of Knowledge, all will degenerate.

Indeed, as soon as any of them regards itself as having attained the pinnacle of desire, the feeling that it is accomplishing all that may be asked of it, so soon will its efficiency cease and the work have to be done by the others—as long as they last. Vanity and laziness are contagious maladies, and if one goes off there is the hazard that the others will follow. Fortunately the relations between the various chemical societies are full of friendliness and good will, and those in authority are men of catholic mind and disposition. Thus are petty jealousies avoided, out of which malice and anger grow. This is a matter of supreme importance, for anger kills the spirit of friendship and cripples progress. With all respect for every religious faith be it said, we have occasionally seen little towns with a dozen or more churches, and these seemed, somehow, to fail in the purposes of their organization, to fall short of establishing that brotherhood of man which leads to the Kingdom of God. A little investigation brought out the fact that each one was officially sure it was right and that all the others were wrong. It is the great good fortune of the scientific societies that they are free from these differences.

Professor Tyndall had a Scotch servant who served him faithfully to the end of his days. Every morning he rapped upon his door and said: "A-r-r-rise, Sir, a-r-r-rise! 'Tis seven o'clock an' ye have a g-r-r-reat wor-r-rk to do this day." Now science is so much greater than all the societies, its fields hither and yon are unploughed and uncultivated to so vast an extent, the battle against poverty and waste is so great and victory is so far away, that we have, all of us, a great work to do this day. And from the measure of the tasks which the chemical societies have set for their coming meetings, and the manner in which they are pulling together toward the distant goal, it would seem that they had called the old Scotchman's ghost and were listening to his message.

Made in America

There is a ring to "Made in America" that sounds pleasant in the ears of most of us—excepting importers. We like to read it and hear it, and are disposed to use the first person plural in reference to it, if it relates to that which succeeds. "We" have been leading the world in the iron and steel and copper and zinc and lead industries. "We" have been leading the world in electrochemical industries from the time that industrial Niagara Falls was founded. "We" have been leading in a number of industries of heavy chemicals, and if proof is needed that this leadership is not merely based on tonnage, but that this country can claim to have done its due share in technical improvements, the remarkable progress made in America in recent years in oil refining and cracking processes may be cited as just one example. But all these things are old stories, relating to industries in which this country always has had a decided natural positional advantage. But now since the European war has started, we have become independent of the foreigner even in a remarkable number of our industrial needs which formerly called for aid

from abroad and with respect to which the natural advantage of this country was not so clearly defined as to encourage home production on a large scale.

At the risk of boasting let us consider some of the industries that have either been born or have greatly developed since the war began and the European sources of supply have been shut off. Without attempting to make a complete list or even a systematically classified list, and mentioning them only as they come to mind, there are barium compounds and potash, the latter in insufficient quantity, but growing. Among the most remarkable strides are those made in the manufacture of glassware, the permanent substitution of soda glass for the potash product in electric lamps, and the development of high-grade ware for laboratory and technical uses that was heretofore generally considered hopeless in this country. The same may be said of laboratory porcelain ware. Instead of making "brands" of special steels according to "recipes,"—a condition that had not entirely gone out of vogue when the war broke out—the leading companies are beginning to regard the making of specified steels as a necessary and proper part of their business. More ferroalloys than ever are made in this country to meet urgent requirements. The manner in which a great calcium carbide plant at Niagara Falls was switched over to produce ferrosilicon under stress of need was a shining example of efficiency and good sense. The fireworks man and the automobile wallah, as well as the lecturer on chemistry, need worry no more about the imports of magnesium. They are making plenty of it at several places.

This country has taken the lead in the production of radium and is likely to keep it. Crucibles were made of foreign clays because there was nothing that would serve the purpose to be had here with the old methods—until the United States Bureau of Standards found how to do it. Now, prime quality earthenware and stoneware is made here for nearly every purpose. The ruthless, wasteful and consequently wicked destruction of organic products by beehive coke ovens is diminishing by leaps and bounds, wherefore we should cease to sorrow rather than to boast. Munition works have become leading industries in many places, and this is the only legitimate business that we hope to see curtailed by the circumstances of peace. For a time the daily press was insistent that these should all be turned into coal-tar color works immediately after the war, but we have not heard much of it lately. Possibly this was to be accomplished by the engagement of a chemist to come and say "presto," and thus turn the trick. We know of no better method.

Instruments of precision designed for scientific and technical work are coming upon the market from local makers, and they are good. The dyestuff industry is getting out of its muddle. Many of the larger dye and print works are making their own aniline, aniline salt, and aniline and sulphur colors. The old names like Schoellkopf, National Aniline, Heller and Merz, Hudson River, etc., are familiar, but consider the new ones: Beckers, Swiss Color, Federal Dyestuff, Bull's Ferry, Neidich Process, Butterworth Judson—to mention only

a few of the new producers. We have not heard of a full list of alizarine or fast cotton colors developed as yet, although indigo is produced here synthetically on a small scale. Dulcinea and Hermione may not have been able to match all of their shades of ribbon since the war broke out, but we have seen flesh-colored hosiery that seemed almost too successful in its tint. The demand why "we" do not make our dyestuffs here has lost its imperative quality; "we" do make them.

The list of synthetic products now made in America is growing daily. Among others are salol and the salicylates, sodium benzoate, benzaldehyde and photographic chemicals by the dozen. Pharmaceutical products are coming along; not all of them by any means, but a great many of the standard ones that were formerly imported and a very engaging list of new ones.

The old chemical pot is boiling.

Steel Tonnages "Made in America"

In the case of nearly all of the wonderful improvements that have been made in the manufacture of steel in the past thirty years, a precise statement of "who did it first" would be likely to provoke a controversy. The greatest single invention of them all, indeed, the pneumatic converter, furnished a subject of controversy for years. Bessemer's name was attached to it, but without Mushet's suggestion of the use of manganese it would not "work," while William Kelly of Pittsburgh, working in Kentucky, blew metal before Bessemer, but gave up his investigations because he feared that to develop the pneumatic converter would spoil the fairly lucrative business he already had.

When one thinks of "Made in America" in connection with iron and steel he is, however, on perfectly safe ground if he refers to tonnage. Whoever first suggested or practiced a certain improvement it is in the United States that the tonnages are made. In the production of pig iron here is a brief chart of the race. For many years the United States had made considerably more pig iron than Germany, but in 1875 Germany's metric tons slightly exceeded the gross tons of the United States. Then we have the following:

	United States, Gross Tons	Germany, Metric Tons	Great Britain, Gross Tons
1875	2,023,733	2,029,389	6,365,462
1890	United States passes Great Britain		
1890	9,202,703	4,658,451	7,904,214
1901	United States = Germany + Great Britain		
1901	15,878,354	7,880,088	7,928,647
1903	Germany passes Great Britain		
1903	18,009,252	10,107,901	8,935,063
1913	30,966,152	16 × Germany	3 × Great Britain

To continue the comparison for the period since the war started would not be illuminating as an index to the developments, but it may be noted that in 1915 the United States made as much pig iron as the rest of the world, and this year it will readily maintain the proportion.

While the United States has produced the large aggregate tonnages, it has also produced the large tonnages at individual works. It was in the American works that it was first decreed that the blast furnace should be the servant of the Bessemer converter, that if less silicon would shorten the blow the blast furnace

must make the lower silicon, and thus wonderful records were made by American Bessemer converters. If mills could roll more steel by being made heavier they were made heavier and were given more power.

The development of the Lake Superior ore region is one of many illustrations of how American engineers established new tonnage concepts. When the Panama Canal was being dug the *Canal Record* published statements of steam shovel performance of which the engineers were proud, but for years the Lake Superior region had been doing better with its shovels. Underground mines on the Mesabi range were largely abolished, it being shown that in some instances it would pay to remove 2 ft. of overburden to uncover 1 ft. of ore. The ore-carrying capacity of lake vessels has been doubled almost from decade to decade, until now there is a record of 13,800 gross tons of ore for a cargo, loaded and unloaded in a very few hours. When the ore had to be carried a thousand miles, by rail, water and rail to furnace, it was necessary that everything should be done at the lowest cost per ton.

The American steel industry has given the world some wonderful products. There is the all-steel freight car, and later the all-steel passenger, the latter adopted partly because if accidents cannot be avoided it is well to make them as comfortable as possible. The latest steel coal cars are designed for 120 net tons carrying capacity, the work of a dozen cars abroad. Scores of skeleton steel buildings have been erected in the United States with more than 10,000 tons of structural steel in the framework. The American steel industry furnishes steel for an annual output of 1,400,000 automobiles, vastly more than the output of all the rest of the world, and for this automobile industry it furnishes not only steel of high physical quality, but steel of high surface finish, for the automobile industry is the father of many common descriptions of steel to-day.

In the new industrial future of the United States the steel industry is likely to progress even more rapidly than in the past, but on somewhat different lines. It will take more interest in the refinements of fuel and other economies and in the manufacture of more by-products. In these directions it will be true to its traditions of doing everything on a large scale. The ideas may come from abroad, with or without a "thank you!" but they will be carried out with courage on the broadest lines.

The Bureau of Mines and American Radium Production

Instances of successful and profitable cooperation between the federal government and private enterprise, for the promotion of scientific and industrial research, are not so numerous as to be called readily to mind. In fact the principle has been questioned so frequently, both by individual and organized bodies of professional consultants, that a fairly well defined sentiment exists against the idea. The general proposition is open to debate, of course, and exceptions may be recognized, particularly when such exceptions have become demonstrated facts.

The work of the Bureau of Mines and the National Radium Institute offers a peculiarly happy instance of successful cooperation of the type mentioned; and as the term of that cooperation is drawing to a close we may review the whole experience and observe its effect on American radium production.

The terms of the agreement, in brief, were these: The National Radium Institute was organized by Dr. James Douglas, Dr. Howard A. Kelly and others, for the purpose of securing radium for therapeutic use. The underlying motive was philanthropic. A supply of ore was provided through an agreement with officers of the Crucible Steel Company, who owned carnotite-bearing land in southwest Colorado, and who leased this land to the Institute on a 15 per cent royalty basis, with an agreement to purchase the uranium and vanadium by-products. Then, in order to secure technical ability to operate the treatment plant, the Institute offered to furnish the Bureau with financial assistance to build and operate a mill for the treatment of 1000 tons of carnotite ore. The Bureau was to provide the services of certain of its staff for the technical control of the work. In addition to the opportunity thus afforded the Bureau to make a technological study of radium production, it was to receive any radium in excess of seven grams of anhydrous radium bromide produced from the 1000 tons of ore to be treated.

The results of three years' work now drawing to a close under this agreement may be recapitulated as follows: Approximately 1500 tons of ore and concentrate will have been treated when work ceases about the end of this calendar year. The National Radium Institute already has received its anticipated quantity of radium at a cost far below that indicated by the accepted market price. The Bureau of Mines also has obtained a part of its share and will ultimately receive a substantial quantity of the rare element for research purposes. Public benefits have accrued: An economical method of treatment has been developed for both ore and concentrate, and new radioactive methods of plant control have been devised. Some of these have been made public and all will be disclosed when the work is completed. The uranium-radium ratio has been proved to be in normal equilibrium in carnotite just as in pitchblende—an important fact for American producers. Valuable by-products of rare elements other than uranium and vanadium have been obtained for future study. Finally, as a sequel to the successful work with carnotite, an opportunity was recently offered to make a study of the concentration and treatment of low-grade pitchblende, which will add to our knowledge of radium production in this country. In this latter work the Colorado School of Mines was able to play a cooperative part through the use of its experimental mill.

Of course the personal element must not be overlooked in discovering reasons for the success of this venture. With men of less noble motives and narrower experience in the conduct of metallurgical enterprises, there would have been the chance of endless conflict and ultimate disaster. The times also were propitious with regard to public sentiment toward radium; while the un-

expected cessation of production abroad undoubtedly stimulated an interest in American production of radium from domestic ores. In spite of original opposition which engendered more or less bitter feeling, we seem to have here an example of successful co-operation that justifies the contentions of its supporters. Whether it can be duplicated depends on so many conditions that it can not be taken as criterion.

The Future of Steel Consumption

The marvelous increase in the production and consumption of steel has always been the subject of wondering comment, where will it end? The rule of pig iron production doubling every decade having been so often referred to, while doubt has been expressed in recent years whether the rule is still in force, a precise statistical comparison may prove of interest. The production in the ten years ended last year having been 257,714,701 gross tons, a tonnage of 256,000,000 tons may be taken for the decade, as that figure is susceptible of convenient bisection. We therefore show 256,000,000 with its successive bisections in the first column in the following table, and the actual production in the second column, the statistics for the earlier years not being precise, although amply accurate for the purpose.

Pig Iron Production, Gross Tons

Ten years ended	By rule	Actual
1915.....	256,000,000	257,714,701
1905.....	128,000,000	148,658,012
1895.....	64,000,000	76,061,628
1885.....	32,000,000	32,319,295
1875.....	16,000,000	13,559,866
1865.....	8,000,000	7,951,047
1855.....	4,000,000	6,400,000
1845.....	2,000,000	3,000,000
1835.....	1,000,000	1,600,000

When the figures are considered according to this scheme the rule of doubling is seen to have been followed with remarkable fidelity. The confusing fact that contiguous decades do not show the progress well, is eliminated quite largely by making the comparisons between the alternating decades. The comparison of the decade just ended with the preceding one or two decades would suggest that the rule has lately been losing its force, but if we go back four decades or six decades we find an almost absolute harmony. In dealing with inanimate objects physical and chemical experiments frequently show a much larger discrepancy, and yet are considered valid than is shown by this investigation of what man, in his varying circumstances and moved by various emotions, has done.

The most common explanation of the rapid increase in iron consumption is that of "new uses." In its barest form that is, of course, no explanation at all. Why the "new uses"? To furnish a real explanation there would have to be discoveries, and those discoveries would have had to come by chance, and not through the compelling force of circumstances, which is the usual one with discovery and invention. If circumstances brought forth the new uses, then what were the circumstances? We have had new uses which did not "pan out."

The one great influence in the increase in the use of iron is, after all, a very simple one, readily understood. It is no more nor less than the continued and

rapid increase in the ability of the people to buy, by reason of their increase in numbers and their greater wealth. That, really, has made the skyscraper as well as the automobile. It has made the large consumption of steel in freight cars and locomotives as well as in metal furniture and farm implements. It is the one principle that explains the rapid increase in the use of iron and the one index that one can consider and weigh as to its force in causing a further continued increase in future in the consumption of iron in its various forms.

Labor Conditions After the War

What will happen to all the new chemical works and their business after the war? It is hard to tell what European labor conditions will be. Fighting embitters men and many who are heroic in a dash against an enemy and will watch and wait through long days and nights for a chance to shoot, may, and again may not, be able to work steadily when the raging and the tumult is over. Generally speaking, however, aside from the injury to the mind caused by shock and passion and anger (as brought out by Dr. Crile), military training is good training and fits men for team work.

In this country labor conditions are not improving. There has been bluff, chicanery and the very limit of stupidity practiced by many employers and by many organizations of labor. We have said before and we say it again that the obligation of an employer does not cease when his pay clerk passes out the pay envelopes. General welfare of the men and their families; housing, sanitation, schools and good living conditions must be looked after. One of the severest indictments against an employer that has come under our observation was a crippled father, a mother approaching her end from medical neglect, and a large family of children, all illiterate and under-nourished, returning from the works of a pompous, self-satisfied captain of industry to their native home in northern Italy. There isn't any excuse for this sort of a crime, and it has been practised by sheer omission all too often.

On the other hand, we find an apparently increasing number of labor leaders and agitators who know no gospel save that of hate and destruction; and they have learned the art of leadership. A passion for organization has arisen among the ranks of labor, and once organized, its leading purpose seems to be to strike and to destroy. A fashion of thought which is growing among them is to take all grievances out of the public. If an employer will not grant this, that or 'tother, but more especially if he will not give over the functioning of his authority and judgment in the administration of work which he is paid to supervise, then "pound the public" is the slogan, until he gives in.

A few successful threats have started a season of bluffing extraordinary, and of a kind that has not been dared heretofore. Four railway unions want an eight-hour day, and so their representatives tell the Congress of the United States that unless they get it they will set about to starve the people. And they proudly show their entire conspiracy whereby they have actually

planned to inflict the ravages of hunger and disease upon the people of nearly the entire country unless their demand be granted. Then, instead of arresting the conspirators for planning such an heinous offense, as would have been done a dozen years ago, Congress obeys, and lets the men with the whip write the law! This is rank anarchy. Collective bargaining is just and right and proper, but collective blackmail and collective crime is no more to be endured than a single blackmailer or a single criminal. It is high time that we got this idea into our heads or the lash of the collective whip as a means of blackmail to gain power and advantage for self-organized groups of men, without reference to merit or justice, will destroy far more than property; it will destroy the liberties of all of us, rich and poor alike.

Now this is neither reasonable nor intelligent on the part of labor, nor is it a course to be expected, except as a result of a prevalent fashion or style of thought—and these are very contagious—or because men have been in charge of the affairs of corporations who may have had abundant executive ability but were lacking in character or were too timid to do right. But so long as labor goes by its abstract name and laborers are regarded as hands rather than as men, we cannot expect intelligence to abide in their organizations. The feeble-minded and incompetent are there because no other place has been found for them. There must be jobs for those who are below standard; jobs that pay a living wage and do not provide for the advancement available to entire men. Nobody wants feeble-minded workers in his establishment, but everybody that employs men in large numbers has them. He can't get rid of them; their fathers and brothers and sons will not let them go and the result is, now they are in the works, cutting down the pace and following the lead of every vicious notion that is presented to them, from breaking agreements to cracking skulls. Some place must be found for them and there is no change of turning them to profit; they are bound to be an expense in one way or another.

With the culls eliminated, a working staff can be organized that will beat the world, provided always there is the right measure and quality of brain tissue at the head. Some few concerns seem to be approaching this condition despite heavy labor costs and the reek of disorder in the air.

It behooves chemical industry to make its works attractive to those who earn their living there. Nothing helps more than an enthusiastic, loyal, well-paid working staff that believes in the company and is glad to work for it. We have seen a large part of the match industry in this country changed from an abode of misery, disease and desolation into a splendid, wholesome corps of good citizens who work in it. We find improvements developing among the workers in the iron and steel industries—in spots—that put old conditions to shame. And one of the first obligations of chemical industry, for its own benefit, is so to organize its work that its factory portals shall bid welcome to good men and true, to undertake their responsible tasks in conscience and in loyalty.

Flotation Bubbles

To the Editor of Metallurgical & Chemical Engineering

SIR:—In view of the great interest now taken in the flotation process, the photographs of flotation bubbles and bubble aggregates or froths, herewith reproduced, should be of interest.

Photographs 1 and 2 show the bubbles in the act of lifting the particles of minerals to the surface. They are cross-section views under water and were taken in a glass cell, using a B. & L. microscope and camera. Fig. 1 shows bubbles of a pine oil froth to which are

adhering particles of cassiterite, Fig. 2 pine oil No. 6 froth, the bubbles lifting small particles of galena. The magnification in both cases is 40 diameters.

Photographs 3 to 8 show the froth in a small experimental machine; they were taken from above the machine. All factors affecting the froth were kept constant. The impeller was stopped just before taking the picture. This allowed the small bubbles of some froths to coalesce as shown in Fig. 3 to the formation of large bubbles and as shown in Fig. 5 to the formation of a small bubble scum. The ore used was a dolomitic lead ore. Fig. 3 shows cresylic acid froth, Fig. 4 coal tar

FIGS. 1 TO 8—FLOTATION BUBBLES

creosote froth, Fig. 5 pine oil No. 6 froth, Fig. 6, wood creosote froth (correct amount of oil), Fig. 7 wood creosote froth (with an excess of oil), and Fig. 8 shows wood creosote froth, the same as Fig. 7, after adding oil from water gas tar. The froth has become a scum.

Sources of Metal Loss in Copper Refining

To the Editor of Metallurgical & Chemical Engineering

SIR:—In Mr. Lawrence Addick's paper on "Sources of Metal Loss in Copper Refining," in METALLURGICAL AND CHEMICAL ENGINEERING for July 1 the question of moisture in copper bullion is touched upon. The article in question implies that in the Australian copper on which these tests were first made the moisture came from contact with bilge water during shipment. There is every reason to believe that this moisture was bosh water, consequently refiners of copper have reason to look in copper shipped by rail for moisture, just as much as in that shipped by vessel.

Pacific Coast Waterpowers and Electrochemical Possibilities

To the Editor of Metallurgical & Chemical Engineering

SIR:—In your issue of Aug. 1, 1916, page 115, appeared a report of a meeting on the Niagara Falls Power Famine. In this meeting Mr. F. A. Lidbury, manager of the Oldbury Electrochemical Co. and a Past President of the American Electrochemical Society, stated that electrochemical industries cannot establish on this Pacific coast because of the excessive transportation charges to the territory now supplied by Niagara. Conversely, from this it would appear that if there is a market tributary to this coast Niagara would be out of the running for this business as compared to a plant operating on the coast.

As a matter of fact the market for electrochemical products is world-wide, and the establishing of such a large and varied industry requires the condition of accessibility to the markets of the world, viz., cheap transportation, which condition is satisfied by a location in a good harbor on tide water. There are such locations on the Pacific coast.

The average annual imports of Chilean nitrates into San Francisco exceeds 30,000 tons. To manufacture 30,000 tons of lime nitrate containing about the same amount of nitrogen, would require approximately 40,000 hp.

That California in the year 1912 had orders in Norway for lime nitrate in excess of the entire output of one of the large plants is a statement published in the Hearings Before the House Committee on the water-power bill.

Carbide.—There are probably more than 5000 tons of carbide used on this coast yearly. The establishing of new oxygen plants both in the States of Washington and California indicates an increasing use of carbide. In 1913 Chile imported from Germany over three and a half million kilos and Australia imported 14,155 tons, 85 per cent of which came from Norway and Sweden.

Ferro-alloys.—California is now shipping to the East chrome and manganese ore, and it is only a matter of reasoning that the ferro alloys could better stand high freight rates than the crude ore.

Cyanide.—The Pacific Coast is a more central dis-

tributing point for potassium or sodium cyanide than is Niagara.

Caustic.—At Pittsburg on San Francisco Bay there is now in operation a caustic and bleach plant established by people thoroughly conversant with and interested in similar plants in the East.

To the question: "Why do not electrochemical industries establish on this coast?" I would answer: "They are establishing."

E. P. KENNEDY,

President Speer River Project.

San Francisco, Cal.

The Determination of Chromium in Ferrochromium

To the Editor of Metallurgical & Chemical Engineering

SIR:—The following simple method for the determination of chromium in ferrochromium has proven, after a year's usage, both rapid and accurate.

The procedure consists in fusing the alloy with sodium peroxide, forming Na_2CrO_4 , dissolving the melt, and, after boiling to destroy the excess of peroxide, which has a strong tendency to reduce chromium in acid solution, acidifying with sulfuric acid and titrating the resulting dichromate solution by the usual method with tenth normal ferrous sulfate solution. The following outline is worked out for ferrochrome which contains about 70 per cent chromium: For alloys of different composition one may modify the amount of sample taken or the size aliquot titrated within reasonable limits.

Weigh accurately one gram of finely pulverized alloy (50 mesh) and mix thoroughly with 25 to 35 grams sodium peroxide. This may be accomplished by stirring the mixture with a stiff platinum wire in either a nickel or an iron crucible of about 40 c.c. capacity in which the fusion is to be made. A layer of sodium peroxide is placed on top of the mixture and the crucible gradually heated over a Bunsen burner to a dull cherry red until the contents is entirely fused. The heat is now lowered, keeping the mixture molten at a very dull red, nearly black heat for fifteen minutes. Gradually raise the heat once more to a dull cherry red and then allow the crucible to cool.

Place the crucible and contents in a one-liter beaker with 250 c.c. of water. Cover and allow the reaction to proceed. When finished, remove the crucible and cover carefully, washing with hot water. Boil the contents of the beaker vigorously for about twenty minutes to destroy the excess of peroxide. Acidify with a considerable excess of $\frac{1}{2}$ sulfuric acid and concentrate, if necessary, to a volume of about 300 c.c. Cool and transfer to a 500 c.c. volumetric flask and fill to the mark with water.

An aliquot of 50 c.c. is now titrated in the usual way against freshly standardized N/10 ferrous sulfate solution. This may be conveniently carried out by filling a 100-c.c. burette with the dichromate solution and titrating back and forth until a satisfactory end point is reached. The titration may also be carried out by adding an excess of standard N/10 ferrous sulfate solution to a 50-c.c. portion of the solution prepared for analysis and titrating back to a blue end point with N/10 potassium permanganate solution. This end point may be properly identified by treating 50 c.c. N/10 $\text{K}_2\text{Cr}_2\text{O}_7$ (standardized by pure iron) plus sulfuric acid in the way described.

For the sharpest end point the solution must be perfectly cold.

One c.c. N/10 ferrous sulfate is equivalent to 0.001743 gm. chromium.

The Iron and Steel Market

While September has not brought more active conditions in the steel market than obtained in August it has brought an accretion of confidence that the time when the pressure on the mills for deliveries is a long way off. The scarcity of material for this year's delivery has been accentuated, partly by reason of additional buying and partly by reason of the hot weather being prolonged and causing the curtailed rate of production to obtain for a longer period than normal.

Steel prices have shown a further hardening tendency. Bars, plates and shapes are better established at the advances of a month ago. Iron and steel pipe has been advanced one point, or about \$2 a ton, on butt weld sizes and two points on lap weld sizes, black, no change being made in galvanized. The new cards are dated Sept. 7. An advance in sheets is predicted for the near future, based on the expectation that the fourth quarter price on sheet-bar contracts will be \$3 to \$5 a ton higher than that obtaining for the third quarter.

Production of pig iron was a shade smaller in August than in July. The production in the first half of the year was 19,619,522 gross tons, but during July and August the furnaces fell 190,000 tons short of maintaining that rate, and the curtailed rate bids fair to continue through September. While October, usually a very favorable month for furnace operation, will doubtless show a heavy output, the prospect is that the official statistics will show smaller production of pig iron in the second half of the year than in the first half, although the second "half" of the year contains two days more.

There is no doubt that there was a considerable reduction in pig iron stocks during the first half of the year, while it is also a fact that new open-hearth furnaces have been completed month by month, whereby consumptive requirements certainly increase while it is impossible to make more pig iron. The general influence has not worked out thus far, perhaps, because the hot weather has curtailed the output of steel works very considerably since July 1. It is very easy to conceive an acute pig-iron scarcity developing within the next few months. That would quickly be reflected in the market. From the low point of December, 1914, basic pig iron at valley furnaces have advanced from \$12.25 to \$18, or \$5.75, while billets have advanced from less than \$19 to more than \$45, or in excess of \$26 a ton. If higher prices should be demanded for pig iron the steel works would have no difficulty in finding the money with which to pay.

Exports of iron and steel commodities that are reported by weight amounted to 496,000 gross tons in July, against 526,772 tons in June and 540,549 tons in May, the record month. Exports in the seven months totaled 3,112,000 tons, representing a rate of 444,000 tons a month, or 5,300,000 tons a year. In the same period British exports average 312,000 tons a month, and these exports were made up largely of material for the United Kingdom's allies. Until lately British exports were always greatly in excess of those of the United States.

Iron Ore

By a decision announced Sept. 5 by the Interstate Commerce Commission freight rates from Lake Erie docks to most Central Western points are revised, and on an average there is a reduction. New tariffs are to be filed by Dec. 1, and the new rates are to go into effect April 1, 1917. The rate to the Pittsburgh district is reduced from 88 cents to 82 cents. Monessen is taken out of the Pittsburgh district and given a rate of 96 cents, while on the other side Neville Island is taken

out and given the 70-cent rate which is retained for Aliquippa. Johnstown, formerly with a rate of \$1.02, is classed with Monessen. Wheeling is kept with Pittsburgh. The Pittsburgh rate was formerly 96 cents, but had been reduced to 88 cents when the commission ruled that the rate to Pittsburgh should not be higher than that to Wheeling, then 60 cents. Apart from the pecuniary importance of the decision the outstanding feature is the close application of the yardstick to the map. Only a few years ago the railroads were still insisting that the complicated rate structure would not permit of ton-mileage consideration of rates. The new rates as just stated are not the rates that will be published, as the carriers are required to segregate 6 cents for dock charges, from the rail of the vessel to the car, publishing this 6 cents as a separate rate. Apart from this 6 cents there is 10 cents that is regularly charged the vessel, making 16 cents for unloading direct ore. The commission ruled several years ago that its jurisdiction over iron ore, as interstate commerce, began at the rail of the vessel at lower lake dock.

Wild chartering has lately been done at \$1 a ton clear to the lake vessel, against the regular rate of 50 cents established before the season opened, and it is understood there has been some chartering for next year at \$1. The latest predictions are that Lake Superior ore may be advanced \$1.25, instead of \$1, for the new season, which would apparently give the shipper a net advance of 75 cents, allowing for the increased lake rate.

Iron ore shipments down the lakes in August amounted to 9,850,140 tons, or a gain of 100,000 tons over the July shipments. The season total is now 39,215,864 tons, indicating that about 62,000,000 tons can be moved down the lakes this season, with the usual movement of about 1,000,000 tons by all-rail to the old furnaces, plus about half a million tons consumption by the two Steel Corporation furnaces at Duluth, put in blast for the first time about the beginning of this year, making 63,500,000 tons in all. The record season's movement thus far was in 1913, just a shade under 50,000,000 tons.

Pig Iron Strong

The movement in pig iron has continued, but is more marked in foundry than in steel-making grades. All markets are firm, and some show an advancing tendency. Southern iron is up 50 cents, to \$14.50, Birmingham, regaining half the loss it experienced earlier in the year, and the same is to be said of Chicago, which necessarily moves closely in harmony with Southern iron. Foundry iron at valley furnaces is up 25 cents, to \$18.50. The furnaces may soon conclude they have sold enough of their output at prevailing prices. If a definite scarcity of pig iron should develop, as is far from impossible, the market would advance by dollars a ton rather than by fractions.

Unfinished Steel Very Scarce

Offerings of soft steel billets and sheet bars for this year's delivery are only occasional, and of small tonnage, the scarcity being as pronounced as at any time. The market is purely a nominal one, at say \$45 to \$50. One interest, perhaps more, is selling for first half shipment at \$46 and upward. There are few consumers that could afford to pay \$45 or \$50 for steel, with finished steel prices at their present levels, but a finishing mill in position to profit by the premiums offered for early deliveries of some finished products could afford to do so.

The report seems to be correct that within the past fortnight two steel works have sold about 100,000 tons of billet discards for export, this following similar large

sales of more than a month ago, and it appears that the unwieldy accumulations of billet discards, arising in the manufacture of shell steel, are now quite well worked off. Some of the steel has been bought by consumers who desired the particular grade, but most of it has been taken by buyers who would much prefer to have ordinary soft steel.

Non-Ferrous Metal Market

Sept. 11.—Copper is strong and scarce on early shipments. Tin is unsettled, but prices remain fairly steady. Lead has improved and is in fairly good demand and spelter has also had a slight advance.

Copper.—The copper market is in a strong position and deliveries for the balance of 1916 are held at a higher figure. Scarcely any offers of prompt or September electrolytic are made by the producers, and 28 to 28½c. is asked for the small amounts offered. Domestic buying is good for futures, October electrolytic being quoted at 27.75, with November and December deliveries at 27.25. Export business is dull at the present time, but inquiries for copper are being made by Russia.

Tin.—The tin market is in a very unsettled condition, due chiefly to the difficulty and delay in getting permits for shipments to this country. During the last two weeks there has been alternate activity and dullness and at present the market is dull and easy, with September and October Straits held at 38.40c. November arrivals at 38.35c., and December at 38c. Banca tin is about 1c. under these prices. Deliveries into consumption in August amounted to 4335 tons, somewhat less than the average so far this year.

Lead.—This market is at present in a pretty strong position. The trust price is still held at 6.50c. New York, with independents asking 6.60 and higher for spot deliveries. Sales to Japanese buyers were reported on Sept. 8, and these had the effect of stimulating the market somewhat. Futures are quoted at prices but very little under the spot price.

Spelter.—Buying was on a good scale last week following a previous dull period, and the market closed higher at the end of the week. Prompt and September spelter is quoted at 8¾ to 8⅞c., with fourth quarter at 8⅝c. There is difficulty in securing freight room for export shipments and the market abroad has advanced. Exports in August were large and amounted to 11,352 tons.

Other Metals.—*Antimony* is dull, with Chinese and Japanese held at 12c. No import business is reported on this metal. *Aluminum* continues steady at 61c, *magnesium* is quoted at \$3.50 to \$3.75 per pound, *platinum* at \$60 per ounce, *quicksilver* at \$76 per flask. *Silver* is higher at 63¼c.

American Institute of Chemical Engineers, New York, Jan. 10-13, 1917.

The New President of the Colorado School of Mines

Mr. Howard C. Parmelee, for the past six years Western editor of this journal, has been elected president of the Colorado School of Mines. In extending to him our congratulations, in which we are sure his many friends in all parts of the country will join us, we feel we are not overstating the case if we say that the famous Colorado School is equally to be congratulated on the selection of its new president.

Mr. Parmelee was educated at the University of Nebraska, where he received the degree of B.S. in 1897 and A.M. in 1899. He entered the employ of the Union Pacific Railroad as assistant chemist in their Industrial Laboratory in 1900. From 1901 to 1903 he was chemist

HOWARD C. PARMELEE, PRESIDENT, COLORADO SCHOOL OF MINES, GOLDEN, COLO.

at the Globe plant at the American Smelting & Refining Company. From 1903 to 1906 he was consulting chemist at Denver, Col. He entered editorial work in 1905 as editor of the *Mining Reporter* and continued in this position until 1907. From 1908 to 1910 he was editor of the *Western Chemist and Metallurgist*. In 1910 he became Western editor of *METALLURGICAL AND CHEMICAL ENGINEERING*.

His editorial work gave him wide acquaintance among metallurgical and chemical engineers throughout the country and provided him with an insight into the educational demands of those industries. This was further aided by his great activity in the work of technical societies. Mr. Parmelee was one of the organizers of the Western Association of Technical Chemists and Metallurgists and general secretary of the organization for five years. He is also one of the organizers of the Teknik Club of Denver and its secretary since its organization, about six years ago. He is a member of the American Institute of Mining Engineers, a manager of the American Electrochemical Society, and the president of the Colorado Scientific Society for the year 1916. He has been elected to several honorary scientific societies, Sigma Xi, scientific fraternity, at the University of Nebraska; Tau Beta Pi, engineering fraternity, at the Colorado School of Mines; Alpha Chi Sigma, chemical fraternity, at the University of Colorado.

While we sincerely regret the loss of Mr. Parmelee as active Western editor of this journal, we are glad to state that he has consented to stay with this journal in an advisory and consulting capacity to introduce his successor as Western editor, Dr. S. Fischer, Jr., into the work and insure continuity of editorial effort.

These have been six happy years of friendly editorial co-operation. We cannot express our wishes for Mr. Parmelee's future career better than in the hope that he will meet the big task before him as president of the Colorado School of Mines with the same resolute courage, the same genial resourcefulness, and the same decided success which have characterized his work in the past.

Program of New York Meeting of American Chemical Society

The general program of the fifty-third meeting of the American Chemical Society, which will be held in New York City, Sept. 25 to 30, during the week of the Exposition of Chemical Industries, is as follows:

Monday, Sept. 25

- 2.00 p. m.—Official opening of Exposition, addresses by Dr. Chas. H. Herty, Dr. Francis A. J. Fitzgerald and Dr. Arthur B. Daniels.
- 4.00 p. m.—Council meeting, Chemists' Club.
- 7.30 p. m.—Council dinner, Chemists' Club.
- 9.00 p. m.—Council meeting, Chemists' Club.

Tuesday, Sept. 26

- 10.00 a. m.—General meeting of the society at Horace Mann Auditorium, Columbia University, 117th Street and Broadway. Addresses of welcome by Mayor Mitchell of the city of New York, President Butler of Columbia University. Response by President Herty, followed by general papers.
- 2.00 p. m.—Public meeting, Horace Mann Auditorium, Columbia University. Addresses by speakers of national reputation (to be announced). Presidential address by Dr. Herty.
- 8.00 p. m.—Reception at Hotel Astor. Members American Electrochemical Society invited.

Wednesday, Sept. 27

- Morning.—Divisional meetings, Columbia University, Symposium on Colloids (theoretical).
- Afternoon.—Two industrial conferences. One at the Chemists' Club on American Dyestuff Manufacture and one at Grand Central Palace on Electric Steel.

Thursday, Sept. 28

- Morning.—Divisional meetings, Columbia University, Symposium on Colloids (applied).
- Afternoon.—Two industrial conferences. One at the Chemists' Club on Industrial Alcohol, Acetone, and Formic Acid, and one at Grand Central Palace on Glassware and Porcelain.
- Evening.—Invitation Smoker of the American Electrochemical Society.

Friday, Sept. 29

- Morning.—Divisional meetings, Columbia University, Symposium on Occupational Diseases in Chemical Trades.
- Afternoon.—Two industrial conferences. One at the Chemists' Club on Medicinal Chemicals,

and one at Grand Central Palace on Manufacture of Paper Pulp and By-products.

- 8.00 p. m.—Subscription Banquet at Waldorf-Astoria, members and wives, \$3.50. Guests at cost. The members of the American Electrochemical Society and the Technical Section of the American Pulp & Paper Industry are invited, with price same as to members American Chemical Society.

Saturday, Sept. 30

- Morning.—Meetings of divisions. Industrial Conferences at Chemists' Club on Oils and Motor Fuels. Industrial Conferences at Grand Central Palace on Miscellaneous Chemical Industries, and Convertibility of Plant.
- 11.00 p. m.—Exposition closes at Grand Central Palace.

Program of New York Meeting of American Electrochemical Society

The program of the fall meeting of the American Electrochemical Society which will be held from Sept. 27 to 30, in New York, in conjunction with the Second National Exposition of Chemical Industries, includes many interesting technical and social features. The hotel headquarters will be at the Hotel Astor.

On Thursday and Friday afternoons inspection of the exhibits at the Exposition will be the feature. On Thursday evening a complimentary smoker will be held at the Hotel Astor, to which the members of the American Chemical Society and all other visiting chemists and engineers are invited. On Friday evening a subscription dinner will be held at the Waldorf Astoria under the auspices of the American Chemical Society, to which members of the American Electrochemical Society are invited. The charge will be \$3.50 per plate for members of either society and their ladies. For guests the charge will be cost. On Saturday an all-day excursion will be held up the Hudson by the American Electrochemical Society. Members of visiting societies are invited up to the capacity of the boat.

The detailed program is as follows:

Wednesday, Sept. 27

Electrochemical day at the Exposition, Grand Central Palace.

- 8.00 p. m.—Individual theater parties.

Thursday, Sept. 28

- 9.30 a. m.—Reading and discussion of papers.
 - O. P. Watts and P. L. DeVerter, The Protection of Iron by Electroplating.
 - E. A. and L. T. Richardson, Atmospheric Corrosion of Commercial Sheet Iron.
 - O. C. Ralston and C. E. Sims, The Electrolytic Recovery of Lead from Brine Leaches.
 - H. J. Morgan and O. C. Ralston, Electrolytic Zinc Dust.
 - W. E. Koerner, Electrolytic Behavior of Tungsten.
 - S. Fischer, Jr., Electrolysis of Vanadium Salts.
 - L. D. Hammond, The Electrodeposition of Nickel.
 - F. C. Mathers and E. G. Sturdevant, Current Efficiencies in Nickel Plating Baths with Rotating Cathodes.
 - W. Blum, Deposition of Copper in Electrotyping Baths.
- 12.30 p. m.—Luncheon at Hotel Astor.

2.00 to 6.00 p. m.—Visiting the Exposition.

8.00 p. m.—Complimentary smoker at Hotel Astor.

Friday, Sept. 29

9.30.—Reading and discussion of papers.

C. F. Burgess, Characteristics of Small Dry Cells.

L. C. Turnock, Effect of Temperature on the Performance of the Edison Storage Battery.

Carl Hering, High-Temperature Heat Developed during Electrolysis.

F. A. Fahrenwald, The Possibilities of Developing Superrefractory Materials for Incandescent Lighting.

H. Schlundt, T. H. Leaming and Julius Underwood, Composition of the Ionization Currents Due to Equal Quantities of Radium Emanation.

M. J. Brown, A New Method for the Study of Silver-Peroxynitrate.

W. C. Moore, The Vosmaer Phenomenon.

Grinell Jones and M. L. Hartmann, The Equilibrium between Bromine and Potassium Bromide Solutions at 0 Deg.

12.30 p. m.—Luncheon.

8.00 p. m.—Subscription banquet at Waldorf Astoria under the auspices of the American Chemical Society.

Saturday, Sept. 30

All-day excursion up the Hudson River. Details will be given out at the registration booth, where also the tickets for the smoker and the excursion will be obtained.

The arrangements for the meeting are in the hands of the New York Section of the American Electrochemical Society, of which Dr. Colin G. Fink is chairman and Mr. J. Malcolm Muir, 239 West Thirty-ninth Street, is secretary. Mr. John V. N. Dorr is chairman of the Finance Committee.

Second National Exposition of Chemical Industries

When the Second National Exposition of Chemical Industries opens on Monday, Sept. 25, the public will have an opportunity of seeing collected together under one roof a remarkable collection of apparatus, machinery and products representative of chemical and allied industries. The educational value will be immense, as many processes will be demonstrated in actual operation and moving pictures of various industries will be shown. This is not an exposition which only the technically trained man can enjoy; on the contrary, everyone can find much of interest and value.

One exhibitor will operate a miniature plant making sulphuric acid by the contact process. The American dyestuff industry will be well represented, with raw materials, intermediates, finished dyes and dyed products shown by most of the important companies. One exhibitor will show the process of making one class of dyes, and will operate a complete refrigerating plant for this purpose. One group of chemical companies will show every step in the dyestuff industry—coal, coal-tar crudes, intermediates, dyes, and the alkalis, acids and salts necessary in the various steps.

Electrolytic cells for making caustic soda, chlorine and sodium hypochlorite form another interesting feature. The products of these cells will be shown, and also some of the uses of chlorine in chlorine derivatives, such as carbon tetrachloride, chlorobenzol, etc. A nitric acid condenser will be in operation, the Cottrell electrical precipitation process of removing solids and liquids from gases will be demonstrated, and it will be shown how it can be applied to the recovery of dust in cement plants.

The other features, including motion pictures, the

Bureau of Mines exhibit, the paper and pulp section, the Southern opportunity section, etc., which have already been commented upon in these columns, will prove most interesting to everyone. There are over 50 per cent more exhibitors this year than last, and the attendance will undoubtedly be almost double. The programs of the meetings of the American Chemical Society and American Electrochemical Society, which will be held in conjunction with the exposition, will be found elsewhere in this issue.

Status of New Tariff Law on Dyestuffs

The dyestuff tariff has at last become a law. The Revenue Bill H. R. 16,763, containing the dyestuff schedule, passed the Senate and House after going to conference last week, and was signed by the President on Friday, Sept. 9. It is a good bill in many respects; in one respect it cannot be considered fair to the dyestuff industry in this country, and it may be robbed of its effectiveness by one clause.

The bill as finally adopted was a compromise measure. Coal-tar crudes are admitted free; intermediates are taxed 15 per cent ad valorem and 2½ cents per pound specific; finished dyes, excepting alizarine and alizarine dyes, anthracene and carbazol, natural and synthetic indigo and all indigoids, medicinals and flavors, are taxed 30 per cent ad valorem and 5 cents per pound specific duty. The exceptions noted are taxed only 30 per cent ad valorem.

The bill as it originally passed the House was not entirely agreeable to the Senate, and it was the subject of considerable debate.

A hearing was given by the Senate Finance Committee during the last week in July to three members of a sub-committee of a larger committee originally appointed at a joint conference held in New York in March, (at which were present representatives of practically every industry affected by the dyestuff situation, including manufacturers of coal-tar products and all classes of consumers). This sub-committee made the following recommendation to the Senate committee:

"It is urgently recommended that lines 23 and 24 at the bottom of page 89, and lines 1 and 2 at the top of page 90 (Title V, Sec. 401), reading as follows: 'except natural and synthetic alizarine, and dyes obtained from alizarine, anthracene and carbazol; and natural and synthetic indigo and all indigoids, whether or not obtained from indigo' be omitted. Otherwise the sincere and rational attempt of H. R. 16,763 to establish a coal-tar industry in this country is liable to be entirely frustrated by that parenthetical exception."

The Senate struck out this clause, and provided that the bill be not operative until after the war, and the bill went to conference. After consideration by the conference committee the clause was put back with medicinals and flavors added, and the bill was made effective at once. It finally passed both Senate and House in this form. After five years a yearly reduction of 20 per cent in duty is to be made, and unless the American industry reaches 60 per cent of our consumption in five years the duties become ineffective.

Further parts of the argument presented to the Senate committee by the sub-committee above mentioned, representing practically all the large producers and consumers, are worthy of earnest consideration. The argument continues as follows:

"The bill, after imposing a general 30 per cent duty on colors and dyes embodied in Section 401, the specific rates designed to encourage the foundation of this industry in the United States. This section imposes for a period of five years or more a reduced duty of 2½ per cent on intermediates enumerated in Group 2, and 5¢ per pound on the finished colors and dyes enumerated in Group 3. But, an-

fortunately, the parenthetical exception above referred to cuts out from this special 5-cent duty 'natural and synthetic alizarin and dyes obtained from alizarin, anthracene, carbazol and natural and synthetic indigo and all indigoids, whether or not obtained from indigo.'

"The class of colors thus excepted from the operation of the act constituted 27 per cent in money value of all the dyes sent out from Germany to us in the year 1913 and German exports alone represented more than 80 per cent of the U. S. A. consumption of all colors in that year.

"The terms of the bill provide that the special duty shall cease unless an American industry shall have been built up in five years' time capable of furnishing 60 per cent in value of the country's consumption. This arbitrary deduction of 27 per cent of the industry will make the attainment of 60 per cent of the total, a practical impossibility.

"Nearly eight million pounds of indigo, 20 per cent paste, are annually imported at a value of one and a half million dollars; this is by far the most important single color imported, and no other color approaches a million dollars in value. The two classes—alizarin and indigo—already represent nearly 16,000,000 pounds by weight of our color imports out of a total of fifty million pounds, and if they were permitted to reach our shores at one-half the duty imposed on the others they would soon represent nearly all of our colors. Dyes obtained from anthracene and indigoids comprise every shade of color in the rainbow. The colors thus excepted by the bill may be used on cotton, silk, wool, leather, in making paints or for any other purpose for which the strictly aniline colors may be used. Taken on the average, the colors thus excepted sell at lower prices in the form in which they are sold than the so-called 'anilines.'

"Nearly all of the excepted colors are made either with or by a combination of anilin oil and salts. Turkey red, it is true, may be made without using anilin and indigo may be made without using it, but as a matter of fact, one-half of the indigo in the world is actually made by using anilin and (however made) 70 per cent of the weight of indigo consists of anilin in its final analysis or composition.

"And it is now recognized that the cheapest and most effective way to make indigo is by the use of anilin. And yet under this exception indigo made with anilin would escape the extra duty or surtax. All the other excepted colors contain as much as 30 per cent of their weight in anilin oil or its equivalent.

"And so, as was stated above, these colors dovetail into one another and it will be chimerical to expect to build up an anilin color industry in this country by a specific tariff whilst thus exposing it to attack from colors that contain anilin, compete with anilines and yet under the exception will not be classed as anilin colors.

"Furthermore, it may be stated that for the amount of indigo imported into this country in 1913 there was required 1,000,000 lbs. or 500 tons of anilin oil in its production, and the total anilin oil consumption of the country before the war was but 4,000,000 lbs. This exception, therefore, practically takes back with the left hand what has been given with the right. It presents the anomaly of attempting to build up that most important coal tar industry by a temporary dike or barrier and leaving the dike wide open over 27 per cent of its length.

"The duties provided by the act are at the best barely sufficient to offset in normal times the handicap of German priority and pre-eminence.

"The exclusion of the colors in question would open a way to evade the spirit of the law and would cause endless disputes calling for Treasury interpretations. The consumer would find himself forced to question the derivation of every color imported in the hope that it would be found to be included in the excepted class. Expert witnesses could show that blacks, blues and 90 per cent of all colors may be produced from alizarin, anthracene, indigo and carbazol. The European makers would immediately develop colors produced from the privileged group which have many superlatively good qualities, and soon the new tariff would be found almost as inefficient in building up this industry as we have just found to our cost that the old tariffs have been.

"The collateral importance of this industry must not be overlooked.

"The coal-tar industry has a direct bearing on the steel industry as also on the high-explosives industry, and this last is absolutely essential to national life and safety.

"Unless the coal-tar color industry can be put on a sound, independent and paying basis in this country, it will be impossible for the country to become independent of the world in the matter of those high explosives which are essential for military purposes.

"During the past thirty years a 30 per cent *ad valorem*

duty on so-called anilines, but leaving indigo, anthracene etc., on the free list, has utterly failed to produce any sort of coal-tar color industry in this country except a very small industry which depended on imported intermediates. There is no foundation whatever for the belief that a 30 per cent duty which was ineffective in the case of anilines would be effective to create such an indigo and anthracene industry in this country. The color industry is and should be considered as a whole. If exceptions are made which are to be wholly or partly duty free they would soon grow to be of more importance than the items not excepted, and this could have only one effect—to defeat the very object of the bill. No one would be tempted to invest money in making aniline colors so long as he could be exposed to competition by another group or class of colors paying a much lower duty."

Representative Kitchin of North Carolina, chairman of the House Ways and Means Committee, led the fight in the conference committee against the specific duty on alizarin, indigo, medicinals and flavors, and Ceasar Cone of the Proximity Manufacturing Company of North Carolina, one of the largest users of indigo in the country, persistently fought the duty on these products. Thus it might be said that one factory has won out against consumers and manufacturers employing 2,000,000 people.

The dumping clauses in the section on unfair competition are first-class. Provisions are made for the first time, controlling imports and subjecting importers to all the restrictions of American manufacturers. The anti-dumping clauses are practically the same as when the bill passed the House and Senate before going to Congress. They make it unlawful for any person to import goods and sell them at a lower price than the actual market price in the country of their production.

The actual text of Group III and Sections 83 and 84 are given below. Group I contains a list of the coal-tar crudes—these are admitted without duty—and Group II contains a list of dutiable intermediates. These are omitted.

"Group III. All colors, dyes, or stains, whether soluble or not in water, color acids, color bases, color lakes, photographic chemicals, medicinals, flavors, synthetic phenolic resin, or explosives, not otherwise specially provided for in this title, when obtained, derived, or manufactured in whole or in part from any of the products provided for in groups I and II, including natural alizarin and indigo, and colors, dyes, or color lakes obtained, derived, or manufactured therefrom, 30 per centum *ad valorem*.

"Sec. 83. That on and after the day following the passage of this act, in addition to the duties provided in section 82, there shall be levied, collected, and paid upon all articles contained in group II a special duty of 2½ cents per pound, and upon all articles contained in group III (except natural and synthetic alizarin, and dyes obtained from alizarin, anthracene, and carbazol; and natural synthetic indigo and all indigoids, whether or not obtained from indigo and medicinals and flavors), a special duty of 5 cents per pound.

"During the period of five years beginning five years after the passage of this act, such special duties shall be annually reduced 20 per centum of the rate imposed by this section, so that at the end of such period such special duties shall no longer be assessed, levied, or collected; but if at the expiration of five years from the date of the passage of this act, the President finds that there is not being manufactured or produced within the United States as much as 60 per centum in value of the domestic consumption of the articles mentioned in groups II and III of section 82, he shall by proclamation so declare, whereupon the special duties imposed by this section on such articles shall no longer be assessed, levied, or collected.

"Sec. 84. That paragraphs twenty, twenty-one, twenty-two and twenty-three and the words 'salicylic acid' in paragraph one of Schedule A of section 1 of an act entitled 'An act to reduce tariff duties and to provide revenue for the government, and for other purposes' approved October 3, 1913, and paragraphs 394, 452 and 514, and the words 'carbolic' and 'phthalic,' in paragraph 387 of the 'free list' of section 1 of said act, and so much of said act or any existing law or parts of law as may be inconsistent with this title are hereby repealed."

Glimpses of New Pacific Coast Industries in the Making

Impressions From a Flying Editorial Trip to California

To write down the impressions received on an all-too-short trip to California might seem preposterous, if it were not for the fact that it was just one more trip in a series. While none of these trips was extended enough and thorough enough to permit a complete detailed sketch to be made of what was seen, they all together have left a very distinct moving-picture effect of new Pacific Coast industries in the making. To bring this point out clearly is the object of this note, while more complete accounts of the various new industries are reserved for future issues from the pen of men directly connected with the different undertakings.

After a very hot trip through the Middle West a first stop was made in Denver. Through the courtesy of Dr. R. B. Moore of the Bureau of Mines we visited the radium plant operated jointly by the Bureau and the National Radium Institute. It is a very business-like affair and gives an unexpected impression of bigness of plant and operation. The process was described in detail in a paper by Dr. Charles L. Parsons in our Vol. XIV, page 51 (Jan. 1, 1916). The work will soon be completed and the plant will then be sold or dismantled. We comment on some aspects of the radium work of the Bureau of Mines in an editorial in this issue (page 275).

At Salt Lake City another stop was made and we enjoyed a very interesting forenoon at the University of Utah, where in the Mining Building the station of the Bureau of Mines, under Dr. Dorsey A. Lyon, has its headquarters. We hope to publish in one of our next issues an account from Dr. Lyon's pen of the very far-reaching and manifold researches carried out under his direction during the past two years. These researches have covered the most varied subjects, from flotation to electrolytic zinc and lead, and the recovery of zinc from low-grade ores by igneous concentration, and many other problems. It is a very well equipped laboratory, with some ingeniously designed home-made apparatus. From Dr. Lyon's laboratory more than one well-trained engineer has gone into metallurgical practice, and the industry has been the gainer. One of his most notable co-workers who is still with him is Mr. Oliver C. Ralston, well known to our readers by his work on flotation and electrolytic zinc and lead.

The University Club of Salt Lake City, at which we had the pleasure to lunch with Dr. Lyon, deserves a notice, as it represents a realization of what has been considered an impossibility in other cities. There is a very cozy clubhouse in the best residential street, and yet in most immediate neighborhood of the business life of the city, with library and roof-garden, and all appointments which make a clubhouse homelike. No wonder the financial conditions of the club are said to be the most flourishing of any club in the State.

From Salt Lake City we went straight to San Francisco, and the first side trip to study new developments was made to the Pitt River in Shasta County.

Electrochemistry Along the Pitt River

Pitt is a station, nothing more, on the Shasta route, a little beyond Redding, a night's ride from San Francisco. It serves as the starting point of a small so-called railroad line along the Pitt River up to Bully Hill. One of the stations along the scenically beautiful road is Heroult on the Pitt.

ELECTROLYTIC ZINC AT BULLY HILL

Bully Hill is a famous old mining and smelting center. There are many indications of the primitive opera-

tions from early gold mining days up the Pitt River. There is also the big Bully Hill copper smelter, owned by the General Electric Company, but not in operation now on account of the suit brought by the government for damage done by fumes to vegetation. There we had the pleasure to meet our good old friend Mr. C. A. Hansen, who has temporarily forgotten his old love, the electric furnace, and is busily and enthusiastically engaged in making electrolytic zinc in a large-scale experimental plant. A very interesting account of some of his work at Bully Hill was given by him in our issue of Feb. 1, 1916 (Vol. XIV, page 120). He is not now using rotating cathodes, but some from his former work were there for inspection. It is interesting to note that different ores respond differently to the electrolytic process. Some curious problems with respect to addition agents have come up. The process is to be used on a large scale at the Mammoth Smelter at Kennet (midway between Pitt and Redding), and Mr. Handley of this company has done considerable work on the process.

There is no doubt that electrolytic zinc is attracting very considerable attention. The number of metal-

WHERE THE MCLOUD CREEK JOINS THE PITT RIVER

lurgists from various zinc companies we met at Bully Hill was significant in this respect. We were especially delighted to meet again at Bully Hill the distinguished general manager of Amalgamated Zinc, Ltd., of Broken Hill, Australia, Mr. Herbert W. Gepp.

After much talk with many zinc experts, not all of the same opinion by any means, it would seem no rash prediction to say that electrolytic zinc has come to stay for good.

NOBLE ELECTRIC STEEL COMPANY

Midway between Bully Hill and Pitt lies Heroult-on-the-Pitt. It was sad to think that this is the last that is left in this country of the name of one who up to his death was a very good and true friend, but it is pleasant to say that now at least the place that bears the famous French electrometallurgist's name has become prosperous. The Noble Electric Steel Company has had a hard time in an up-hill fight.

When Mr. H. H. Noble, as president of the Northern California Power Company, with true pioneer spirit conceived the idea of introducing electric iron reduction and steel refining to the Pacific Coast, he had be-

NORTH FORK FEATHER RIVER, CAPABLE OF PRODUCING 600,000 HP.

sides cheap power (\$12 per horsepower-year) one very big asset—a really magnificent iron ore and limestone mine. This mine is still the biggest asset of the company.

The plant was started by Dr. Paul Heroult, who was assisted by Mr. N. Petinot, and pig iron was successfully made. Then came a series of administrations, each characterized by a new furnace design. They were all carefully worked-out designs, but they all proved commercial failures. Each of these furnaces was worked for a time and subjected to improvements, but had finally to be abandoned. Most of the furnaces are still there, and the part of the plant where they are is something like a furnace museum.

If at this late date we may venture a reason for this succession of failures, we believe we are right in saying that everyone of the different furnace designers tried too much and wanted to make efficiency a maximum at once. It was overlooked that the first aim must be to make the furnace work in continuous foolproof operation, and that when this is accomplished there will be time to look after finesses in the saving of heat units and other improvements. In trying to make a furnace theoretically perfect from the start, one is liable to introduce mechanical complications which will be fatal in operation.

It is to the great credit of the present manager of the Noble Electric Steel Company, Dr. W. W. Clark, to have recognized this fundamental principle, and to have made a complete success of the plant. Since he started operation of the first furnace on April 15, 1916, for making ferromanganese, it has been in continuous operation. Mostly ferromanganese has been made, but when there occurred a lack of supply of manganese ore, the furnace was switched over for the time being to pig iron making. Other ferroalloys have also been made, and it is the intention to go into ferrochrome manufacture, since it is recognized that ferromanganese made in the electric furnace is a war baby. It is also intended to make special steels.

The electric furnace now used is of utmost simplicity of design. In this respect Dr. Clark has gone back to the principle of Dr. Heroult, "simplicity first." It looks as though Dr. Clark is going to make a reputation for himself as a first-class operating man at Heroult-on-the-Pitt, and Mr. Noble deserves our hearty congratulations on the final success of his pioneer work.

A delightful automobile ride over the Cascade Mountains to Redding concluded an ideally perfect day.

A New Industrial Center of Growing Importance on San Francisco Bay

The chief trouble with San Francisco as an industrial center has been in the past the labor problem—the domination of the labor unions. (During our present visit it was the union of waiters and chefs of the many restaurants that were on strike, and on entering Tait's or Techau's we were told by red-ribboned gentlemen and ladies that no fair-minded man should patronize a place unfair to organized labor.) But the labor problem must be solved if San Francisco is to come to what is due to her as a manufacturing city in view of the many obvious very great positional advantages.

San Francisco Bay is already an industrial district of no small importance, and its importance is rapidly increasing. One of the best locations is Pittsburg, at the outlet of the Sacramento and San Joaquin Rivers into San Francisco Bay. It has tidewater transportation, besides three railroads, and it has fresh water supply from the two rivers. It is there that the new plant of the Great Western Electrochemical Company is located about which more will be said later, also the works of the Henry Cowell Lime & Cement Company. Then if we pass along the shore of San Francisco Bay, there are the General Chemical Company of California, the A. L. Smith Lumber Company, the Columbia Steel Company, the refineries of the Union Oil Company, Shell Oil Company and Arroc Oil Company, the Selby Smelter and the Mountain Copper Company, the Hawaii Sugar Company, the Giant Powder Company, the Hercules Powder Company, the Standard Oil Company (having here the largest single oil refinery in the world), and the Stauffer Chemical Company.

This is quite an impressive list as it stands. It shows that the positional advantages of the district are clearly recognized. If we add that in the near future considerably more electric power will be available on tide-water for which there will be no use for lighting, traction and domestic purposes, because the present supply for these purposes is sufficient, then with an excess of electric power available at reasonable rates the incentive to go into new manufactures is self-evident.

This brings us to the new power development of the Great Western Power Company.

GREAT WESTERN POWER COMPANY

It has been argued *a priori* (by a distinguished engineer in a report to his very distinguished company) that no permanent hydroelectric power could be had in California on account of its two seasons, the dry season and

POWER PLANT OF GREAT WESTERN POWER CO. AT LAS PLUMAS

the wet season. But this argument completely overlooks the possibility of regulating the flow of the rivers and storing the water in artificial lakes during the wet season and drawing it off during the dry season.

An excellent example is the development of the Great Western Power Company.

The power of the Great Western Power Company is derived from Almanor Lake—an artificial lake with an area of something like 20,000 acres, in the Feather River Canyon district, a three hours' ride by automobile from Keddie on the Western Pacific. This lake now covers what was formerly the "Big Meadows." By building a comparatively short dam in one corner of the valley it was possible to produce this artificial lake.

The present power house of the Great Western Power Company is at Las Plumas on the Feather River. It has a developed capacity of 60,000 kw., which may be increased to 80,000 kw. or 110,000 hp.

The new development, which is now under way, will utilize the same water in another fall near Belden, where a drop of 2000 ft. is available. This will yield 250,000 hp. so that the total will be 360,000 hp. It is hoped that this development will be completed in about a year.

By developing still other falls, the total that could be developed from the same water could be brought up to 600,000 hp. Besides, more water could be made available.

The interesting point is that the same water is made to work here in several plants in succession and moreover that after it has been used repeatedly for power development, it is finally used for irrigation in the Sacramento Valley where a 100-ft. irrigation canal has been built for watering rice fields; this will form eventually a transportation canal from the Sacramento River to Oroville. In view of this situation it might almost be said that the name Great Western Power Company is a misnomer in so far as it is a water company rather than a power company.

The Great Western Power Company has a splendid organization. At its head is Mr. Mortimer Fleishacker, who is also president of the Angelo-California Trust Co. and of the Great Western Electrochemical Co.—one of California's ablest constructive financiers. Mr. E. W. Beardsley is general superintendent and Mr. W. W. Briggs general sales agent. Mr. J. M. Howells, the hydraulic engineer of the company, is also the father of the company in that he discovered the possibility of creating the lake and built the dam. Mr. J. W. Beckman

GREAT WESTERN ELECTROCHEMICAL CO., PITTSBURGH, CAL.

is the chemical engineer of the company looking for uses of power in electrochemical plants. Thus Mr. Howells and Mr. Beckman may be called the pioneers of the head and the tail of the company.

To Mr. Beckman we are indebted for some unforgettable delightful days along the Feather River with a grand auto trip from Keddie to Almanor Lake and over to the Belden Trail (Yellow Creek trail) where the new 2000-ft. fall is to be developed. Our thanks for courtesies received are also due to Mr. Roberts in charge at Almanor Lake and to Mr. Cane and Mr. Menzel in charge at the power house in Las Plumas.

GREAT WESTERN ELECTROCHEMICAL COMPANY

The Great Western Electrochemical Company is an outcome of the conviction that if all the power which can be made available by the Great Western Power Company is to be utilized an outlet must be found in electrochemical industries. Mr. Mortimer Fleishacker is the president; Mr. John F. Bush (formerly general manager of the Hooker Electrochemical Company) is vice-president and general manager; Mr. J. W. Beckman is chemical engineer.

Ground was broken for the new plant at Pittsburgh on San Francisco Bay in February, 1916, and operation was started in the latter part of July for the production of caustic soda and chlorine by electrolysis of brine. The capacity is 2500 hp., the output 5000 tons of caustic soda and 10,000 tons of bleach. Experiments are under way for the manufacture of other chlorine products. Power is obtained from the Great Western Power Company at very reasonable rate.

The Moore Allen cell is employed. This is a diaphragm cell used by the Jessup & Moore Paper Company; it is very similar to the Townsend cell, but no oil is used.

The bleach made is sold principally for paper bleaching in the Pacific Coast States and in Canada, but as an indication of the peculiarities of the present time it may be said that some of the bleach has been sold to Sweden and Norway.

The caustic soda is sold chiefly to plants at San Francisco Bay, part of it in liquid form.

Messrs. Bush, Beach & Gent are the sales agents of the company. While caustic soda and chlorine are the first products of the company, the intention is to enter other electrochemical industries. Mr. Beckman has a vision as to the electrochemical possibilities of the Pacific Coast and he is strongly backed by the industrial and financial genius of Mr. Fleishacker. The develop-

BIG MEADOWS DAM FORMING LAKE ALMANOR, SHOWING SPILLWAY AND OUTLET TUNNEL, NEXT LARGEST ARTIFICIAL LAKE IN THE WORLD

ment of the company deserves close and friendly attention.

OTHER NEW DEVELOPMENTS AT SAN FRANCISCO

At Oakland, across the Bay, the Electro Alkaline Company has been operating for some time a small plant of twelve Whiting cells for the production of hypochlorite. With present prices the business is highly profitable.

In Visitation Valley, San Francisco, the Rankin process for fixation of atmospheric nitrogen is tried out in a 1000-kw. furnace, after experiments in a smaller furnace had been made in Nevada. No definite results can yet be announced. Mr. E. B. Bumsted, a civil engineer of San Francisco and the present president of the San Francisco Engineers Club, is backing the venture.

At the Berkeley station of the Bureau of Mines under Dr. Duschak much attention is paid at present to the cause of explosions which have occurred recently and repeatedly in oxy-acetylene welding plants along the Coast.

Mr. E. J. Fowler of the Pacific Foundry Company has made a great success with his non-corrosive "corrosion," while from Mr. E. L. Oliver of the Oliver Continuous Filter Company, we learn that his filter is entering the chemical field.

The chemical industries are moving in California, and it is a pleasure to watch them. Even a hurried business trip, with some things to worry about (not the least being the threatening railroad strike), is a source of continuous delight in sun-kissed California.

(A second article on Southern California developments will follow.)

Exhibitors at Chemical Exposition

In the following we give an alphabetical list, complete up to Sept. 13, of the exhibitors at the Second National Exposition of Chemical Industries, to be held in the Grand Central Palace, New York City, in the week of Sept. 25, 1916.

Abbe Engineering Co.; Abbe, Paul O.; Alberene Stone Co.; American Chemical Society; American Coal & By-Product Coke Co.; American Electrochemical Society; American Institute of Mining Engineers; American Synthetic Dyes, Ltd.; American Transformer Co.; American Synthetic Color Co., Inc.; Angel & Co., H. Reeve; Arnold, Hoffman & Co.

Badger & Sons Co., E. B.; Baker, J. T., Chemical Co.; Barber Asphalt Paving Co.; Barrett Company, The; Bausch & Lomb Optical Co.; Beckers, W., Aniline & Chemical Works; Beighley Electric Co.; Benzol Products Co.; Bethlehem Foundry & Machine Co.; Bristol Co., The; Brown Instrument Co.; Buffalo Foundry & Machine Co.; Butterworth-Judson Corporation.

Carborundum Co.; Carrier Engineering Corporation; Castner Electrolytic Alkali Works; Carolina, Clinchfield & Ohio Ry.; Celluloid Zapon Co.; Central Foundry Co., The; Chadwick-Boston Lead Co.; Chemical Catalog Co.; Chemical Co. of America; Chemists' Club, The; Coatesville Boiler Works; Codd Co., E. J.; Condensite Co. of America; Contact Process Co.; Corn Products Refining Co.; Corning Glass Works.

Day Co., J. H.; De Laval Separator Co.; Denver Fire Clay Co.; Detroit Range Boiler Co.; Devine Co., J. P.; Dorr Company; Dow Chemical Co.; Downington Mfg. Co.; Driver-Harris Wire Co.; DuPont, E. I., DeNemours Co.; Duriron Castings Co.

Edison, Thos. A.; Eimer & Amend; Electro Bleaching Gas Co.; Electrochemical Co., The; Electron Chemical Co.; Electrolytic Zinc Co., Inc.; Elyria Enamelled Products Co.

Fabra Co., Ltd., The; Foote Mineral Co.; Foxboro Co., The; Franco-Swiss Colours Co.; Freeport Sulphur Co.; Fuller Engineering Co.

Geissinger Regulator Co.; General Bakelite Co.; General Chemical Co.; General Electric Co.; German-American

Stoneware Works; Glens Falls Machine Works; Golden Chest Mine; Great Western Power Co.; Great Western Silica Co.; Greiner Co., Emil, The.

Hardinge-Conical Mill Co.; Harrison Bros. & Co.; Hemingway, Frank, Corporation; Hayward & Co., S. F.; Herold China & Pottery Co., The; Holz, Herman A.; Hooker Electrochemical Co.; Huff Electrostatic Sep. Co.; Huyck & Sons, F. C.

Industrial Filtration Corporation; Industrial Research Co.; International Equipment Co.; International Glass Co.

Kieselguhr Co. of America; Kleinschmidt & Co., F.; Koppers Co., H.; Koven & Bro., L. O.

Laboratory Supply Co., The; Lead Lined Iron Pipe Co.; Leeds & Northrup Co., The; Lehigh Car, Wheel & Axle Works; Lehigh Foundry Co.; Lehigh Stoker Co.; Lenz & Naumann, Inc. (American Apparatus Corporation); Life Saving Devices Co.; Little, Arthur D., Inc., Boston; Lungwitz, Emil E.; Luzerne Rubber Co.

Madero Bros.; Manufacturers' Record; Marden, Orth & Hastings Co.; Merck & Co.; Metals Disintegrating Co., The; Metallurgical & Chemical Engineering; Mathieson Alkali Works; Mine & Smelter Supply Co.; Mississippi River Power Co.; Monsanto Chemical Works; Mott, J. L., Iron Works; Multi-Metal Sep. Screen Co.

Nash Engineering Co.; National Aniline & Chemical Co.; National Gum & Mica Co.; Newark Department of Docks and Meadows; Newport Hydro-Carbon Co.; Niagara Alkali Co.; Nitrogen Products Co.; Norton Co.

Ohio Pottery Co.

Palo Company, The; Paper, Inc.; Paper Trade Journal; Patterson-Allen Engineering Co.; Pennsylvania Salt Mfg. Co.; Pfaudler Co., The; Precision Instrument Co.; Process Engineers, Ltd.; Product Sales Co., The; Prest-O-Lite Co., Inc., The; Pyroelectric Instrument Co.

Raritan Copper Works; Raymond Bros. Impact Pulverizer Co.; Research Corporation; Roessler & Hasslacher Chem. Co.; Ruggles-Coles Engineering Co.

Schaeffer & Budenberg Mfg. Co.; Schaum & Uhlinger, Inc.; Schutte & Koerting Co.; Scott & Co., Ernest; Scientific Materials Co.; Semet-Solvay Co.; Seydel Mfg. Co.; Sharples Specialty Co.; Shriver & Co., T.; Sidco Co. of America, The; Society of Chemical Industry; Solvay Process Co., The; Sowers Mfg. Co.; Squibb & Sons, E. R.; Stamford Mfg. Co.; Standard Aniline Products, Inc.; Stevens-Aylsworth Co.; Stone & Webster Eng. Corp.; Stuart & Peterson Co., The; Sturtevant Mill Co.; Sweetland Filter Press Co.; Swenson Evaporator Co.; Swiss Colours Co., Inc.

Takamine Laboratory; Taylor Instrument Companies; Technical Association of Paper & Pulp Industry; Tennessee Power Co.; Tennessee Coal, Iron & Railroad Co.; Textile Colorist; Thermal Syndicate, Ltd., The; Thwing Instrument Co.; Toch Bros.; Tolhurst Machine Works.

Uehling Instrument Co.; Union Sulphur Co.; United Gas Improvement Co.; United Lead Co. (Chadwick Boston Lead Co.); United States Bureau of Mines; United States Cast Iron Pipe & Foundry Co.; United States Bureau of Standards; United States Smelting Co.; Universal Fibre Co., Inc.

Valley Iron Works.

Weiller Mfg. Co.; Werner & Pfeleiderer Co.; West Pulverizing Mach. Co.; Westinghouse Elec. & Mfg. Co.; Whittall Tatum Co.; Williamsburg Chemical Co., Inc.

Zapon Leather Cloth Co.; Zarembo Co.

Chilean Nitrate Statistics for July

Chile's production and exportation of nitrate during July were both on a large scale according to *Commerce Reports*. There were produced in all the oficinas 5,312,776 Spanish quintals (of 101.4 lb. each) and the exports amounted to 5,674,088 quintals.

The market at Valparaiso, where almost all the transactions in the sale and resale of nitrate take place, was not very active during the month, and the change in price was slight. At the end of the month ordinary, or 95 per cent, nitrate was quoted for sale at about 7s. 5d. (\$1.80) per quintal alongside for delivery in the latter part of 1916. Nitrate for delivery in 1917 is held about a penny (\$0.02) higher per quintal. Refined nitrate, 96 per cent—1 per cent, sold as high as 7s. 10d. (\$1.90) per quintal, but for 1917 delivery concessions from this price down to about 7s. 8d. (\$1.87) were spoken of.

The Processes of the Organic Chemical Industry Used in the Manufacture of Intermediate Products

BY A. H. NEY AND D. J. VAN MARLE

There are six raw materials, derived from coal-tar or obtained in the by-product recovery of the coke-oven industry, from which the large number of the intermediate products are obtained. These six products are benzol, toluol, xylol, naphthalene, anthracene and phenol.

By submitting these raw materials to the action of different chemicals in succession, it is possible to obtain from one raw material different intermediate products. By changing the order in which we let these chemicals act, or by changing the proportions or physical conditions (especially the temperature), we are able to obtain different intermediate products with the same chemicals from the same raw materials.

The nature of the operation depends on the chemical we use, so that the action of one chemical on different products is very similar from a mechanical standpoint, and the apparatus in which the operation is carried out is essentially the same.

The most important operations are:

Nitration, carried out by means of nitrating or mixed acid, a mixture of nitric and sulfuric acid, by which the material acted upon is converted into a nitro-compound, and often followed by a reduction, transforming the nitro-compound into an amido-compound by the action of iron and hydrochloric acid.

Sulfonation, carried out by means of sulfuric acid of different concentration, by which sulfonic acids are formed, which are often converted into hydroxyl compounds by a caustic fusion, viz., by fusing with caustic soda in open kettles or in autoclaves under pressure.

Due to the chemical constitution of the products, often different products are formed in one operation. In the benzol-, toluol-, and xylol-series we distinguish these products as ortho-, meta-, and para-compounds, and as a rule either the meta- or the ortho-, and para-compounds are formed almost exclusively. From naphthalene two different products can be formed, the alpha- and beta-compounds. When more than one chemical agent acts on one of the raw materials, the situation becomes more complicated, and in most cases a mixture of different products is formed, which has to be separated. The anthracene compounds form a class by themselves, as the product obtained therefrom are dyes themselves, and they will therefore not be taken into consideration. The derivatives of phenol mostly are not prepared from phenol, but from compounds of the benzol-series, so that the whole field can be divided into two parts, the benzol- and the naphthalene-compounds.

A few examples will illustrate what has been said, and show how it is possible to obtain many intermediate products from these few raw materials.

By nitration of benzol nitrobenzol is formed, but by using the double amount of nitrating acid, the nitration can be carried further, and we obtain meta-dinitrobenzol, which contains two nitro-groups. By reduction of nitrobenzol, it is converted into aniline. Reducing meta-dinitrobenzol, however, we can prepare two products by reducing one nitro-group or both, which is possible by the use of a different reducing agent. With sodium sulfide only one nitro-group is reduced, and meta-nitraniline is formed; with iron both nitro-groups are reduced, converting meta-dinitrobenzol into meta-phenylenediamine.

To prepare the respective para-compounds, para-nitraniline and para-phenylenediamine, we have to start

from aniline, which first is converted into acetanilide by means of glacial acetic acid, then nitrated. The nitro-compound on saponification yields para-nitraniline, and after reduction para-phenylenediamine. A small amount of the ortho-compound is formed during the nitration, the less the lower the temperature is kept.

That the order in which the chemicals act can have a decided influence on the product formed can be shown by the action of chlorine gas on benzol, forming chlorbenzol, which by nitration is converted into a mixture of ortho- and para-nitro-chlorbenzol. Nitrating benzol first, and chlorinating the nitrobenzol, we obtain meta-nitro-chlorbenzol.

In the naphthalene series the temperature is the deciding factor on the nature of the product formed, as by sulfonating naphthalene both alpha- and beta-naphthalene-sulfonic acid are formed, the latter mostly at high temperature, the former at low temperature.

By caustic fusion we can obtain the alpha- and beta-naphthol, the latter operation only being carried out commercially. Sulfonating beta-naphthol it is theoretically possible to obtain seven different beta-naphthol-sulfonic acids, but only two are formed. By a larger amount of sulfuric acid two disulfonic acids are obtained, and in both cases it depends on the temperature, which one predominates in the mixture.

The classes of compounds members of which are of commercial value are:

Nitro-compounds, containing the NO₂ or nitro-group.

Amido-compounds, containing the NH₂ or amido-group.

Chlorine-compounds, containing the Cl or chlorine group.

Hydroxyl-compounds, containing the OH or hydroxyl group (phenols and naphthols).

Alkyl-compounds, containing the CH₃ or methyl group, or C₂H₅ or ethyl group.

Acetyl-compounds, containing the COCH₃ or acetyl group.

Acids-compounds, containing the COOH or carboxyl group.

Sulfonic acids, containing the SO₃H or sulfonic acid group.

Aldehydes and ketones, containing the CO or carbonyl group.

They are generally obtained by the action of nitrating acid (nitration), iron (reduction), chlorine (chlorination), caustic soda (caustic fusion), alcohol or other agents (alkylation), acetic acid (acetylation), carbonic acid (carboxylation), or sulfuric acid (sulfonation) respectively.

These operations we will now discuss more in detail.

Nitration

By the action of nitric acid on organic compounds of the aromatic series, a group of products is formed which are called nitro-compounds. The action of nitric acid consists in the replacement of a hydrogen atom by the NO₂ or nitro-group. In a few cases not a hydrogen-atom but another group, such as the sulfonic acid- or carboxyl-group is replaced. Examples of practical interest being the nitration of the alpha-naphthol sulfonic acids, which are formed by sulfonation of alpha naphthol, and are converted into dinitronaphthol or its sulfonic acid, commercially known as Naphthol Yellow S., and the nitration of phenol-trisulfonic acid, which is converted into picric acid, all three sulfonic acid groups being replaced by nitro-groups.

It is possible to replace more than one hydrogen-atom by a nitro-group, but in most cases not more than three are replaced, in this way forming mono-nitro, dinitro and trinitro compounds. The preparation of mono-

nitro-compounds is comparatively easy, but it is more difficult to make a second or third group enter, and especially in the last case a certain excess of nitric acid is required, and it is necessary to increase the concentration of the acid and to carry the separation out at a higher temperature. Much heat is generated during the reaction, and the reaction, therefore, has to be kept under control by means of artificial cooling.

In the benzol series three different nitro-compounds can be obtained, the ortho-, meta- and para-compounds. It depends on the groups already present in which position the nitro-group enters, and as a rule it enters in meta-position to a nitro-, sulfonic acid, carboxyl- or carbonyl-group, and in ortho- and para-position to a chlorine-, bromine-, alkyl-, amido- and hydroxyl-group. The proportions in which the ortho- and para-compound are found depend to a large extent on the temperature, the para-compound being formed in increasing amount of lower temperature. In case two or more groups are already present, it is hard to predict which compound will be formed owing to conflicting influences of these groups, and often a mixture of different compounds will be the result of this nitration. In most cases a fairly homogeneous product will be formed, and by-products will only be present to a small extent, so that a nitration is one of the operations which is carried out in the organic chemical industry with the greatest success.

In the naphthalene series two different nitro-compounds can be formed, the alpha- and beta-compound. The nitro-group here enters almost exclusively in alpha-position, a second nitro-group entering in position 5 or 8 to the first. In case any sulfuric acid groups are present, the nitro-group enters by preference in position 3 or 8 to one of these groups.

NITRIC ACID

The form in which the nitric acid is generally used, is as nitrating acid or mixed acid, which is a mixture of nitric and sulfuric acid. During the reaction water is formed, which tends to dilute the acid, and in case straight nitric acid is used the acid would become so dilute that it would be no longer effective, necessitating the use of an excess of nitric acid to complete the reaction, which excess, on the other hand, may cause a small amount of higher nitrated products to be formed, which would cause serious trouble in subsequent operations.

The sulfuric acid present in the mixture will bind the water formed during the reaction, and the nitration can, therefore, generally be carried out with the theoretical amount of nitric acid, which also means a considerable saving, as nitric acid is much more expensive than sulfuric acid, and the waste acid, which contains only a small amount of impurities, can be mostly recovered and used for other purposes. The greatest advantage, however, is that whereas nitric acid has a strongly corroding effect on iron, the action of nitrating acid is only slight, and allows it to be shipped in drums, and to carry the nitration out in cast-iron kettles, which makes it possible to manufacture this class of products on a large scale. The presence of sulfuric acid also makes it easier to keep the reaction under control, and the only disadvantage is that much heat is generated by the water which is formed and the sulfuric acid, which causes a material loss of time, as most nitrations have to be carried out at low temperature.

In certain cases the sulfuric acid determines the place in which the nitro-group enters the molecule, and its presence, therefore, can be objectionable unless a method is adopted to counteract its influence. This can be best illustrated with the example of the nitration of aniline, which gives amido-benzol, and from which two

important products are derived, meta- and para-nitraniline. The amido-group directs the nitro-group in para- and to a smaller extent in ortho-position, but as it has basic properties, it forms with the sulfuric acid an acid sulfate, which causes the nitro-group to enter also in meta-position, so that the result of the nitration is a mixture of three products, which would have to be separated. By first converting aniline into acetanilide, its acetyl-compound, by means of acetic acid, it is possible to neutralize its basic properties and prevent the formation of acid sulfate, so that now almost exclusively the para-compound is formed. The meta-compound can be obtained in an entirely different way, as we shall see later.

The nitrating acid, which is generally used, is a mixture of 1 part of nitric acid with 1-2 parts of sulfuric acid, but in a few cases where it is required to use a much more concentrated acid, the nitric acid can be mixed with fuming sulfuric acid, which is cheaper than using a mixture of highly concentrated nitric acid with sulfuric acid.

The nitric acid may be replaced by its salts, such as sodium nitrate, which when mixed with sulfuric acid forms nitric acid and sodium bisulfate, but as this causes mechanical difficulties, it is not often practised, even though it would be cheaper.

There is one class of products, those containing a hydroxyl group, such as phenol and alpha-naphthol, which react very violently with nitric acid and are easily oxidized. Dilute nitric acid already converts them into their nitro-compounds, and the nitration of phenol by means of dilute nitric acid has been carried out on a commercial scale, as the para-compound is used in the manufacture of para-amido-phenol. This process has been abandoned, however, as a much larger amount of the ortho-compound is formed and another way of preparation has been found. The dinitro-naphthol and trinitrophenol or picric acid are of much value, however, and in order to obtain these products, the naphthol and phenol are first converted into the sulfonic acids, the sulfonic acid groups being replaced by the nitro-group and any oxidation being prevented.

TEMPERATURE

In contradistinction to sulfonation, the temperature in nitration has no influence on the nature of the reaction-product, and is only of importance in regard to its purity. In the first place at higher temperature the nitration may be carried further, so that a small amount of a higher nitrated product may be formed, which, as already pointed out, may cause difficulties in subsequent operations. In the second place nitric acid is an oxidizing agent, and especially at high temperature the oxidizing action becomes more pronounced, and part of the material may be converted into products which are entirely valueless, which causes a loss of material and makes purification necessary. The presence of sulfuric acid, which tends to the formation of nitrosyl-sulfuric acid, a compound with strong oxidizing properties, also may cause oxidation, and it is therefore of the greatest importance to keep the temperature sufficiently low to prevent this action, especially when the material to be nitrated is easily oxidized. The oxidation is accompanied by the development of nitrous fumes, which may cause still more complications, in case the material to be nitrated can be reacted upon by nitrous acid. For example, the amido-compound, which may be converted into diazo-compounds and later in the process into hydroxyl-compounds, and the alkylated amido-compound and hydroxyl-compound, which are able to form nitroso-compounds by the action of nitric acid.

For this reason it also is advisable to protect the

amido- and hydroxyl-groups, and the least expensive way is to convert them into their acetyl-compounds by means of acetic acid, which can be easily saponified, in order to obtain the nitro-compounds. Formic acid and for the amido-compounds benzaldehyde also may be used for this purpose.

Much heat is generated during the reaction, partially due to the presence of sulfuric acid, and it therefore is necessary to supply the vessels in which the nitration is carried out with a cooling jacket, which serves at the same time as heating jacket, in case it is necessary to raise the temperature at the end in order to complete the reaction.

Last, but not least, the temperature should be kept under control, as at higher temperature the reaction may become too violent, which may cause serious explosions, two of the products of this class, picric acid and trinitrotoluol, obtained by nitration of phenol and toluol respectively, being used in enormous quantities as military explosives.

APPLICATION

The largest application for the nitro-compounds is found as intermediate products in the manufacture of amido-compounds. The simplest and best known member of this series is nitrobenzol, obtained by nitration of benzol, and converted by reduction into aniline. Enormous quantities are yearly produced, the production of aniline in the United States now being 15,000 tons, requiring the production of approximately one and one-half times its weight of nitrobenzol, to which has to be added the large amount used as solvent and for the manufacture of benzidine. Starting from toluol, xylol and naphthalene we obtain the intermediate products for toluidine, xylidine and naphthylamine, which are applied to a large extent in the manufacture of many azo-dyes, and themselves again can be converted into other valuable products. The nitration of toluol yields a mixture of the ortho- and para-compound, which can be separated by fractional distillation in vacuum, and freezing out the para-nitrotoluol from the residue. The para-toluidine has a larger value than the ortho-compound, while the para-nitrotoluol-sulfonic acid also is used in the production of the stillbene-dyes. The ortho-nitrotoluol can be converted into tolidine, which in its properties is very similar to benzidine. Commercial xylol is a mixture of ortho-, meta-, and para-xylol, which on nitration forms a mixture of not less than five nitro-xylols, of which the meta-compound is present in the largest amount and also is the most valuable. A separation here is not carried out.

Other nitro-compounds which are further reduced to amido compounds are those of benzol-sulfonic acid, acetanilide, dimethylaniline, benzoic acid, salicylic acid and benzaldehyde, used for the manufacture of metanilic acid, para-phenylene-diamine, dimethyl-meta-phenylene-diamine, amido-benzoic acid, amido-salicylic acid and amido-benzaldehyde respectively. Nitro-benzaldehyde itself is also used in the preparation of certain dyes of the triphenylenethane series.

On further nitration dinitro-compounds are formed, the most important being dinitrobenzol and dinitrotoluol, in the last case the ortho- and para-nitrotoluol both being converted into the 2-4 dinitro-toluol, the ortho-compound at the same time forming a small amount of the 2-6 dinitro-toluol. Naphtalene on the contrary forms only one mono-nitro compound, but two dinitro-compounds, the 1-5 and 1-8 dinitronaphtalene, the first to a much smaller extent, but of larger value as it forms by treatment with zinc and concentrated sulfuric acid naphtazarine or alizarine-black, a very fast chrome-black. It has been tried to make use of

the 1-8 dinitro-naphtalene by making a sulfur-black from it, which however has not been able to compete with other blacks of this class.

Nitro-compounds are also used in the manufacture of azo-dyes, para-nitraniline, obtained by nitration of acetanilide, followed by saponification, being used in large quantities. When combined with beta-naphthol, para-red is formed. This dye being insoluble it is prepared on the fibre and can also be used in the paint-industry. It is remarkable that when a small amount of one of the beta-naphthol-sulfonic acids is added a much bluer shade can be prepared. The nitro-toluidine derived from para-toluidine also gives a valuable red lake. Para-nitraniline also is used for developing a number of azo-dyes on the fibre, which improves their quality.

Much attention has also been paid to the nitration of chlorbenzol, as the nitro-chlorbenzol by heating with caustic soda forms nitrophenol, which can be reduced to amidophenol. The para-amidophenol is of value as a photographic developer, and important medicinal products, like phenacetine are derived from it. Originally para-nitrophenol could only be made by nitration of phenol, when a much larger amount of ortho-phenol is formed, aside from the fact that the nitration had to be done with dilute nitric acid. The ortho-nitrophenol can be used for making anisidine and dianisidine, but for large quantities no outlet could be found. Dinitrochlorbenzol, when fused with sodium-polysulfide gives one of the best sulfur-blacks, which is now largely produced in the United States. When combined with para-amidophenol or dimethylaniline before fusion it will form a valuable sulfur-blue.

In the naphtalene-series nitrations are of importance for the manufacture of alpha- and naphthylamine-sulfonic

NITRATOR WITH COOLING TUBES—1600-GAL. SIZE

acids and amido-naphthol-sulfonic acids which belong to the most important constituents for many azo-dyes. By nitration of alpha-naphthol and its sulfonic acids nitro-compounds are formed, which themselves are used as dyes, those being known as naphthol yellow. This is the only practical application of a nitro-compound as a dye, others having been superseded by dyes with more desirable properties.

To this class of products also belong two explosives of high value, trinitrotoluol and trinitrophenol or picric acid, of which the high importance at the present time is well known.

APPARATUS

The nitrations are carried out in cast-iron kettles surrounded by a cooling jacket, and provided with an agitator. Even if not entirely necessary, it is preferable to build the kettles of acid-resisting cast iron, which last much longer than those of ordinary cast iron.

As the raw material can be a liquid or a solid, there are two different ways of carrying out the nitration. If it is a liquid the nitrating acid is run into the raw material, in the other case the acid being put in the kettle first, and the material being added gradually. The materials have to be weighed out accurately, a measuring tank placed on a platform scale being provided for this purpose, for the acid and the liquid material.

In most cases neither the raw material nor the nitro-compound mix with the acid, so that to prevent the formation of two layers an efficient agitator, run at high speed, has to be provided, as insufficient agitation will result in an incomplete nitration, and may allow the nitrating acid to accumulate without acting on the material. In this case the nitration may start suddenly and control may be lost of the operation. There are two types of agitators which have given satisfaction, one consisting of a right- and left-handed propeller, the other of a screw conveyor placed inside a cylinder. Nitrators are built up to 1600 gallons capacity, the larger sizes being provided with a series of tubes, suspended from the cover, through which cooling water is circulated, as jacket cooling here would be insufficient. Every tube is operated individually, and can be replaced in case of leakage without interfering with the operation.

According to the nature of the product, there are three ways of separating this from the waste acid. A liquid nitro-compound is separated from the acid in a lead-lined tank with conical bottom, and collected in a storage tank; a nitro-compound of low melting point can be separated from the acid after it has solidified in a flat, lead-lined tank, while a nitro-product of high melting point can best be separated on a suction filter or by means of a centrifugal, if necessary after diluting the nitration-mixture in a lead-lined tank. The waste acid can be recovered, and concentrated or used for other purposes. In all cases the product is washed with water to remove the last parts of acid.

A number of products like dimethylaniline and acetanilide are dissolved in sulfuric acid before nitration. In this case as in that of the sulfonic acids, where the sulfonation mixture is directly nitrated, the nitration mixture is a homogeneous liquid from which the nitro-compound can be obtained by diluting with water in a lead-lined tank, and sometimes by the addition of salt. The nitro-product is filtered off in a wooden filter press or on a suction-filter, according to its nature and washed free of acid.

Most of the nitro-compounds are reduced without purification. In many cases, where it is crystalline, small amounts of impurities, which adhere to it in a

liquid form, can be separated in a centrifugal. In a few cases where a purification of the product is necessary, this will depend on the nature of the product and the impurities.

In recent years different patents have been taken out, in which a process for continuous nitration has been described, which would make it possible to nitrate large quantities of material in a small inexpensive apparatus. The only product for which this process would be of interest would be nitrobenzol, as others are not produced in sufficiently large quantities. The apparatus consists of four small jacketed nitrators with high-speed agitators. The first and second ones are cooled, the last one is heated. The benzol and nitrating acid are introduced simultaneously in the first kettle in the correct proportions. The kettle is connected to the next one by a siphon, which is arranged in such a way that when the mixture reaches a certain level, it is gradually withdrawn at the bottom and flows into the second kettle, then into the third and the fourth, from which it runs into a separating tank. If this interesting process has found application on a large scale is not known.

Conventions of American Foundrymen's Association and American Institute of Metals

This is foundrymen's week at Cleveland, Ohio. Both the American Foundrymen's Association and the American Institute of Metals are holding their annual conventions, and under their joint auspices there is a big exhibition of foundry equipment, supplies, machine tools and accessories.

The programs of the technical sessions are very full. One session per day is held by either association. Among the papers there is a symposium on the results of closer co-operation between the engineer and the foundry, another one on the influence of gating on castings, another one on electric furnace practice. Some of the papers presented before the Institute of Metals are printed elsewhere in this issue.

Among the exhibitors may be mentioned the Armstrong Cork Company of Pittsburgh, Pa.; the Beighlee Electric Company, Cleveland; Brown Hoisting Machinery Company, Cleveland; Carborundum Company, Niagara Falls, N. Y.; Charles J. Clark, Chicago; Cleveland Blow Pipe & Manufacturing Company, Cleveland; Davis, Bournonville Company, Jersey City, N. J.; Joseph Dixon Crucible Company, Jersey City, N. J.; General Electric Company, Schenectady, N. Y.; Gisholt Machine Company, Madison, Wis.; Goldschmidt Thermit Company, New York; Hauck Manufacturing Company, Brooklyn, N. Y.; Herman A. Holz, New York; Imperial Brass Manufacturing Company, Chicago; Julius King Optical Company, New York; Lakewood Engineering Company, Cleveland; H. M. Lane, Detroit; Life Saving Devices Company, Chicago; Lincoln Electric Company, Cleveland; Monarch Engineering & Manufacturing Company, Baltimore; Multi-Metal Separating Screen Company, New York; Norton Company, Worcester, Mass.; Pangborn Corporation, Hagerstown, Md.; Prest-O-Lite Company, Indianapolis; Pyrotecrite Company, Chicago; Robeson Process Company, New York; Searchlight Company, Chicago; Sullivan Machinery Company, Chicago; Titanium Alloy Manufacturing Company, Niagara Falls, N. Y.; Union Steam Pump Company, Battle Creek, Mich.

Among the entertainment features will be a trip to a ball game Tuesday afternoon, a theater party Tuesday evening, an inspection trip to the Cleveland Blast Furnace Co.'s plant on Wednesday, and other trips.

Design of Factories for the Manufacture of Dyestuffs

By Percival Robert Moses, E. E.

President of Moses, Pope & Messer, Inc.

The great war, imposing as it did a practical prohibition of imports of dyes into this country, has caused a rapid development of the dye industry, but there seems to be a general lack of appreciation of the fundamental facts in connection with the design of plants for this industry, due to a lack of knowledge of the special problems to be met and solved, and as many of these problems have come before us in the design of such factories, an article on the subject of the design of factories for manufacturing dyes and chemicals appears to be timely, and probably useful to those contemplating building.

It goes without saying that under the existing conditions, with a famine existing and with dyes commanding prices more than 1000 per cent higher than the prices before the war, almost any kind of a plant, operated in almost any kind of manner should be able to make money, provided sufficient capital is available to tide over the period of making and correcting mistakes, but after the existing conditions cease the plants which have not observed the fundamental requirements for efficient manufacture will undoubtedly go to the wall.

GENERAL PROCESS

The general process of dye manufacture involves the mixing and heating of liquids, or liquids and gases or liquids and solids; the evaporation, crystallization and distillation of the resulting solutions, accompanied by filtering, drying and grinding in order to produce the finished product. The materials used are largely the products of the distillation of the light oils contained in gas or in tar, such as benzol, toluol, xylol, phenol, naphthaline, anthracene and solvent naphtha. From these are made a host of intermediates, such as betanaphthol, alpha-naphthylamine, anilin oil, and alizarine. These intermediates and the final dyes are formed by sulfonating with sulphuric acid, chlorinating by dry chlorine gas, nitrating with nitric or mixed acids. Acetic acid and hydrochloric acid are also used in connection with iron filings and zinc dust for reducing the nitrated bodies. Large quantities of caustic soda and caustic potash, when this is available, are used for melting the salt formed and removing the sulphuric acid. Lime, soda and occasionally potash are used for changing insoluble into soluble salts, and for neutralizing free acid.

In general, the process is one resulting in the formation of vapors and fumes, and as these are frequently extremely corrosive and in some cases explosive, and in still other cases dangerous to life, the problem of transferring liquids and holding these liquids in storage during the processes and preventing the vapors from escaping into the room or into the atmosphere in an objectionable state is one which has given rise to an immense amount of trouble, most of which could have been avoided with proper knowledge of chemical properties and substances and the material used to hold and convey them.

The same conditions make the problem of fire prevention of special moment. Hardly a week goes by without news of some chemical plant exploding or burning up. This problem can best be met by separate buildings for all processes requiring open fire and isolation of all processes using explosive or easily ignited materials, such as benzol, alcohol and gasoline.

Besides these special requirements, the nature of the processes result in chemical reactions which frequently develop heat, in which case it is necessary to cool the

solutions by cold water or in many cases by artificial refrigeration, and in some particular process artificial refrigeration is not sufficient, and ice must be made and used to get the benefit of the absorption of heat due to the latent heat freed in the melting of ice.

The proper and economical heating of the liquids lends itself to the development of the highest efficiency in the utilization of the energy in fuel. Heat is required in three degrees—if the term may be used—high, medium and low temperature heating. For example, in the sulfonation of one of the intermediates a temperature of around 350 deg. C. is required. This can only be obtained—as the product is inflammable—by the use of a highly heated circulating medium in the jacket, surrounding the kettle, such as oil or superheated steam. For this temperature nothing but direct fire will suffice to heat the circulating medium, or waste gases from other sources.

Moderate temperatures, however, are used to a large degree for distillation, boiling and evaporating. This can best be obtained by the use of exhaust steam from the power plant, which may be operated at a sufficient back pressure to give the desired temperature. In one of the plants we recently completed, turbines were installed and operated at a back pressure of 15 lb. per square inch and an initial pressure of 140 lb. The turbine, of course, used a very large amount of steam per kilowatt hour output, but as all the exhaust steam was afterward used for evaporating purposes the turbine acted merely as a reducing valve between the boilers and heating service, and the power was obtained substantially as a by-product of the supply of heat for the evaporating processes.

Low-temperature heating, such as heating of the building, heating of water—large quantities of hot water being required in the processes—can also be best furnished by the use of exhaust steam, the plan adopted varying in different instances, depending on conditions; for example, one of the power units may be arranged to exhaust at the lower back pressure required by the low temperature heating, or if there is only one power unit in operation, the lower pressure exhaust may be obtained from the lower stage of the steam turbine, or the 15-lb. back pressure line may be provided with an automatically controlled release into the lower back pressure line.

The condensation from the coils is returned to the boilers, or if there is danger of contamination a heat exchange may be effected by the outgoing condensation and the cold water on its way to the hot water heating tanks.

Reference has already been made to the need of refrigerating plants, and in the large dye plants these are of great importance, running up into the hundreds of tons capacity. Such refrigerating plants, and the condensation of the vapors in multiple effect evaporators and the reflux condensers require large quantities of water suitable for condensing purposes. It is, therefore, an essential requirement in the choice for a site for the plant that abundant water be available for condensing purposes. The water to be of such character as will not cause undue corrosion to the condenser, or scaling.

Abundant water, but not necessarily of the same character is required for the solutions, for boiler feeding and for washing filter presses and filtering apparatus. Compressed air is also necessary. It is used for blowing the acids from the tank cars into the storage tanks, and from these to the various measuring tanks, also for lifting liquids by means of montejus, and for blowing out filter presses, for agitating, and if oil is used as fuel, compressed air is used for atomizing the oil.

The plan of a dye plant is, therefore, very complex, as it contains all the apparatus required in the ordinary manufacturing establishment with the addition of refrigerating machinery, and elaborate ventilating systems. The materials used must be carefully selected to withstand the liquids and gases to which they are subjected, and the matter of fire prevention, as has been mentioned, is one of greatest importance and of considerable difficulty.

There is another question which is of vital importance in connection with the success or failure of the plant. A very large proportion of raw materials as compared with finished product is required in almost all these operations. For example, in the production of beta naphthol or phenol, approximately 16 tons of raw material, if the coal is included, are required for the production of one ton of finished product.

This condition carries with it several important sequences. The first is that the location of the plant under competitive conditions will spell success or failure, other things being equal. An advance in freight rates of 10 cents per 100 lb. is equivalent to from 1 to 2 cents a pound on the finished product, and on materials which are sold in great bulk, such as sulphur black and the intermediates this sum may represent the entire profit on the sale.

It is essential, therefore, that the plant shall be located so as to enable it to obtain its raw materials at the lowest possible cost, and for this reason a location on the water front where the freight rates are kept down by competition with water shipments, is essential, unless it is possible with some particular type of dye to locate close to a plant producing the greater part of the raw material required, in which case a saving on the freight rate on one material may make up for the higher freight rates on the other materials purchased. But the question of freight rates is one which should be considered and studied with the utmost care.

The second sequence is that the handling of all this raw material must be done with the minimum of labor. This means automatic handling of the coal and ashes, large storage tanks with compressed air for delivering acids and other raw materials (liquids) and in some cases pumps must be used to avoid danger of explosion. The material in transit should be handled by conveyors wherever possible or pumped, and provision should be made for the discharge of some waste products and the storage of others, pending the development of by-products from them.

This question of delivery of the products in transit from one part of the process to another is also one which involves problems not usually met in the ordinary manufacturing plant. The materials in transit are frequently materials which would tend to clog up the pipes or channels, and in such cases the size of pipes must be made large enough to minimize the difficulty, and clean-outs must be provided at every turn of the pipe, and space left for easily getting at these clean-outs.

In other cases materials tend to solidify (or freeze) in transit, and in these instances several methods are adopted depending on the nature of the materials, as for example, surrounding of the pipe carrying the material with a steam jacket, or where this is not necessary, with insulating covering, or in some cases by the injection of steam.

Many of the liquids carried are extremely corrosive, and this difficulty can only be met by choosing the type of material which is least subject to corrosion, as for example the use of lead pipe for weak sulphuric acid, iron pipe for fuming acid, silver or tin or enamelled lined receptacles for acetic acid; earthenware, glass and special acid-resisting irons have all their special advan-

tages and disadvantages which must be considered in determining the best solution for this part of the problem.

BUILDINGS

Building construction will depend upon local conditions, *i.e.*, the comparative cost of brick or concrete or brick and concrete and steel. For many of the processes, mill construction may be used, but generally speaking wooden construction should be avoided, and as between the other types of construction—the less exposed steel work the better, because of the corrosive action of the fumes of sulphuric acid and hydrochloric acid.

Where alkali fumes are present to any extent, wooden construction should also be avoided, so that on the whole a brick structure with possibly a reinforced concrete skeleton if cost conditions make this possible is the most satisfactory.

Such a building can be put up in New York for from 6 cents to 10 cents per cubic foot, which is equivalent to from \$1.80 to \$3.00 per square foot as the average height of such buildings will be about 30 ft.

The buildings are usually single-storied, part of them being high and part low, the high parts being used to accommodate the many-storied platforms necessary to permit gravity operation.

The other requirements of the buildings are little if any different from the ordinary factory construction. Good light is advisable but not as necessary nor advisable as it is in textile or similar mills. In fact, it is as well from a fire standpoint not to have any more glass than is necessary for the proper carrying on of the operations and in some chemical operations too much light is objectionable.

Ventilation is of the utmost importance, and besides the special ventilation required for the processes such as the liming, nitrating, dissolving in acid, and similar operations, good general ventilation must be provided. Many of the fumes are poisonous, and of course these may be led directly away and not allowed to mix with the general atmosphere. A great deal of vapor is evolved and wherever possible it is collected directly at the apparatus such as the liming tub and led through ducts out into the open air, but in many cases this is not possible. For this reason, good general ventilation is essential.

Where the processes of evaporation and crystallization are carried on in open pans it is frequently essential to prevent any dropping back of condensation from the roof or hood, as this may carry with it impurities sufficient to discolor the whole solution. This is particularly the case if any iron work is exposed.

PIPING

As every dye or chemical factory is liable to change from one product to another according to market conditions, it is usual to arrange the piping in stacks or headers with additional outlets provided at frequent intervals by means of plugged tees or elbows. These groups or stacks of piping include cold and hot water, waste, high, moderate and low (exhaust) pressure steam, condensation returns, compressed air and gas. Acids, benzol, toluol, etc., are usually piped directly to the apparatus supplied unless there are several kettles performing the same operations, in which case headers are run.

Each material requires a particular kind of piping, as already noted in the general discussion.

APPARATUS

The same requirements as to choice of material in piping apply to apparatus. Standard apparatus for the

various processes are gradually being evolved but as the work other than the tubs and tanks consists mainly of casting and sheet metal work, we have found it better to design each piece of apparatus, such as sulfonators, nitrators or reducers, making the sizes, outlets and supporting arrangements comply with the specific needs of the plant.

Of course, we have adopted general designs for these pieces, and as far as possible these comply with the standard patterns of the manufacturers, but as most of the work is in the stage of evolution in many processes, there are no standards and new apparatus has to be developed from a basis of knowledge of processes of a similar character and information of the materials to be distilled or otherwise treated.

In all this work knowledge of chemistry is essential and the designing engineer should have with him a chemist to inform him of the probable reactions and the chemical effects occurring at each stage, including in chemical effects not only the gases, liquid or solid evolved but the heat developed and the temperature required to be maintained.

Questions of agitation are also important, as the profit on any product will depend under competitive conditions, other things being equal, on the percentage of yield, and this in turn will hang in many operations on the completeness of the mixture and the maintenance of correct temperatures during the process. This question of yields is most important and is the one most frequently forgotten in lay discussions. Almost any good organic chemist can produce a product, but unless the yield approximates the yield obtained by others, the process may be considered a failure.

While a great deal of delay, difficulty and loss has been occasioned by insufficient knowledge, poor workmanship and undue haste on the part of manufacturers of apparatus, the good ones are gradually becoming known and with the wider development of the industry keen competition will not only reduce the present abnormally high prices, but it will result in much better product.

Even under existing rush "war order" conditions, carrying with them labor unrest and hurried work, it is possible by careful inspection and selection to secure reasonable safety in the purchase of apparatus.

ELECTRICAL WORK

Many of the vapors affect insulating materials, and where wiring is exposed to destructive fumes it should be lead-coated. Otherwise the standard rubber and double braid insulated wire is satisfactory if enclosed in conduits, which, however, should be thoroughly protected by painting with suitable paint, such as "P & B" or asphalt paint, particularly at the couplings and outlet boxes.

Alternating-current motors of the brushless type are necessary where inflammable vapors exist, and as these

usually exist in some part of the plant, alternating-current is universally adopted. Motors must be of the squirrel-cage induction type wherever inflammable vapors exist or other fumes make it inadvisable to use sliding contacts as required in variable-speed alternating-current motors or in alternating-current motors designed for low starting current. Wherever possible, however, synchronous motors are used to bring up the power factor and over all efficiency. Care must be taken in the location of switch boxes, auto starters and oil-cooled transformers, as with many processes the fumes have chemical effect on the oil and in several cases coming within our own personal experience, motors have burned up and fires have started due to the chemical reaction between the oil and the fumes.

TYPICAL PLANT

The drawing reproduced above shows one of our recent layouts of a chemical plant which is producing two intermediates, with provision for the manufacture of two more in the immediate future.

A brief discussion will perhaps serve to illustrate the points mentioned.

The essential requirements taken care of are that the storage of inflammable materials such as benzol, and alcohol, is kept away from fire hazard, and the departments in which these chemicals are used are kept in entirely distinct buildings from the buildings housing the fusion and distilling operations requiring open flames. The buildings containing the inflammable materials are also kept as far as possible away from danger from locomotive sparks and the construction is essentially fireproof.

Provision is allowed for expansion of the plant by having ample area and by providing space around the buildings so that each building may be added to without interfering with the others.

All the power, steam and compressed air is derived from a central plant which permits of ready expansion of the manufacturing plant and also permits the efficient utilization of all the energy contained in the fuel

by making use of the exhaust steam from the operations of electrical manufacture and the making of compressed air.

Steam is supplied at 150 lb. from the boilers and at 15 lb. from the exhaust of the turbines and at 2 lb. from the other exhausts.

Railroad sidings, storage tanks with capacity for receiving tank-car quantities in addition to the necessary operating reserves together with conveyors and elevators for coal delivery to storage and from storage to the boilers take care of the handling of the raw materials at the minimum cost.

As far as consistent with the separation of the processes requiring flame from those requiring only steam and water, the process is routed on a straight line and where material has to be moved from one building to another because of the separation of processes, the handling of material is done by conveyors and elevators.

For the purpose of economy in handling and also to reduce the cost of piping and avoid stoppages, wherever it is possible to do so, the kettles or filters discharging into tubs are placed directly above the tubs into which they discharge. The measuring tanks which measure the liquids delivered into the kettles are placed above the kettles. This involves in some cases three and four-story platforms, but pumping is avoided with all its manifold objections. Wherever it is necessary to draw from tubs or tanks to discharge through filters or into overhead apparatus, it is our practice to use montejus instead of pumps as montejus require little if any attention. They operate with great rapidity and as they only use power when in operation they are far more efficient than the wasteful steam pump with its continual leakage and its low steam efficiency.

The plant discussed also complies with the requirements mentioned in the beginning of the article, as it is located on the shores of a large body of water which assures an ample supply of good condenser water and pure water for other purposes. The proximity of the plant to the source of supply of benzol, toluol and other raw materials, together with the competition offered by water shipments assures low freight rates for the other raw material not produced near at hand.

The problem of fire protection is solved by the segregation of the buildings, separation by fire spaces and the maintenance of water pressure by elevated tank and chemical fire extinguishers located throughout the plant, together with the usual safeguards required by the insurance companies, such as wire glass windows, fire-proof doors, etc.

The location is also a good one from the point of view of labor. The other requirements are also satisfactorily met, viz.: that labor shall be available at reasonable prices and that there shall be comparative freedom from restrictions as to the making of nuisances such as smells caused by the fumes and disposal of waste materials. Two specific instances have come to our knowledge where failure to consider the nuisance question is necessitating the removal of the plants.

COSTS

It is impossible to give any data on costs which will be reliable for any particular process.

The cost of the half dozen plants with which we have had to do, however, runs from \$150.00 to \$175.00 per ton of finished product per year, exclusive of buildings and from \$300.00 to \$350.00 a ton including land, buildings, water supply and power plant.

These prices are 1915-1916 prices and are probably higher than those that will obtain when normal conditions recur.

In some of these plants, the process starts from an intermediate such as anilin oil or a crude base such as naphthalene or benzol. In all cases the heavy acids, sulphuric, mixed and acetic were purchased and the products made were the simpler ones having large bulk sales. As these intermediates are themselves used in further processes to produce the finished dyes, it becomes necessary greatly to increase these figures when complex dyes are contemplated, as these involve many sulfonations, nitrations, filterings, washings, reducing, etc., and the recovery processes for the recovery of the various reducing agents and the efficient utilization of waste products are so many separate chemical processes.

The industry has already developed its feeding industries, i.e., the producers of caustic soda by the electrolytic process have added chlorination plants for making the monochlorobenzol used in the making of blacks; coke oven plants have added benzol, toluol and xylol and solvent naphtha recovery plants and are extracting their naphthalene and no doubt will soon be making the other crude bases such as anthracen and alizarine.

The importance of the industry to the United States cannot be measured by the tonnage or value of the dyes or intermediates produced.

The total present needs of this country are estimated at from 35,000 to 40,000 tons a year, but this means that use will be found for three or four hundred thousand tons of sulphuric acid, largely a byproduct of other processes; possibly 100,000 tons of caustic soda; thousands of tons of benzol, toluol, naphthalene, etc., and the production of these quantities of these materials means that the United States will be in a position to supply its own needs for defense if occasion should arise.

All these things are not only possible but they are probable, and observance of basic requirements and efficiency in planning together with protection against different standards of living and unfair competition are all that are needed for the development of a dye industry capable of supplying the needs not only of this country but of a fair share of the world.

The International Nickel Co. has acquired additional land at Bayonne, N. J., and will enlarge its plant at a cost of \$500,000.

Electric Welding at Electrical Exposition.—Electric welding of iron and steel will be one of the exhibits of the New York Electrical Exposition, which will be held in Grand Central Palace, New York City, Oct. 11 to 21. The exhibit is being arranged by the Arc Welding Machine Company of 220 West Forty-second Street, New York City, and Mr. O. A. Kenyon will be in charge. The public will have an opportunity of seeing all grades of welding accomplished in iron and steel, including structural pieces, plates and castings. Two arcs will be in operation equipped with automatic control so that the metal cannot burn by drawing too long an arc. The length of the arc is automatically controlled so that even the most unskilled worker cannot draw it beyond the point set. A special type of self-regulating generator designed particularly for welding purposes will be used. It consists of three units, one of which supplies the power, another of which regulates for constant current, and a third which takes care of the adjustment. This generator is used exclusively by the Arc Welding Machine Company. The United States Government is co-operating in the Electrical Exposition through the War, Navy and Commerce Departments, all of which will have comprehensive exhibits.

The Selection of a Method of Ore-Treatment

BY GEORGE J. YOUNG

Professor of Metallurgy, Colorado School of Mines

Present Methods of Ore and Mineral Treatment

Methods of ore and mineral treatment are broadly divided into (1) mechanical methods in which the mineral substances retain their identity, and (2) chemical methods in which one or more of the mineral substances are changed into other compounds. Mechanical methods consist of hand-picking, wet concentration, dry concentration, amalgamation, magnetic separation, electrostatic separation and flotation. Chemical methods are divided into smelting methods and those in which a solution of an active chemical agent like potassium cyanide or sulphuric acid is used to dissolve the valuable mineral.

The simplest mechanical methods are hand-picking and washing. Coal, iron ore, barytes and kaolin have their impurities removed by these methods. Hand-picking is frequently resorted to for the purpose of removing rich lumps of mineral from gold, silver, copper, lead, zinc, or other ores.

Next in complexity is wet concentration. In its crudest form it is used for the treatment of alluvial ores of gold, tin, platinum, and alluvial material containing monazite, rare earths and diamonds. The mechanical treatment of gold, silver, lead, zinc and copper ores involves more elaborate machinery and a much more complicated cycle of steps. Where wet concentration methods, which depend primarily upon differences in specific gravities of the constituent minerals of the ore, do not give satisfactory results, flotation, magnetic and electrostatic separation, which depend upon physical properties other than specific gravity, can be considered and their suitability determined.

Of the solution methods the cyanide process is easily of the first importance. It is used for the treatment of gold, silver and gold, and silver ores. Not infrequently wet concentration is used in conjunction with it. Next in importance is the leaching of oxidized copper ores by the use of solutions of sulphuric acid. While many solution methods have been proposed for the treatment of ores other than gold and silver, it is worthy of note that no one of them has passed beyond the experimental stage with the exception of the acid-leaching of copper ores. The field is, in spite of this fact, a promising one.

Smelting methods are applied to iron, copper, gold, silver, lead and zinc ores. Where ores are "high grade" they frequently are sold to smelters without preliminary treatment. In the case of "low-grade" ores some mechanical method as indicated before is necessary in order to prepare a rich product which is sent to the smelter for treatment.

The Examination of Ores

The examination of ores for the purpose of determining methods of treatment is in itself a common enough procedure and involves methods which are well known and in most cases easily applied. The elaboration of a systematic method of examination has the advantage of bringing to a student the possibilities of the problem and compensating for his lack of practical experience. There have been relatively few attempts to do this, and it is my purpose to present such a system and discuss its limitations.

Taking the Samples

Few ore deposits are uniform, and the samples which are to form the basis of our examination must be taken with the view of representing, as accurately as samples can represent, the extremes of variation and the averages of the ores which have been exposed in the mine workings. The deposits may present three distinct divisions,

the upper or oxidized portion, the intermediate or enriched portion, and the lower or primary portion. In some cases the ore problem may concern all three zones, while in others the oxidized portion may be relatively insignificant and the enriched portion important, or both the oxidized and enriched portions important and the primary zone unimportant. In other cases the primary zone may be of greatest importance. The relative importance can be determined by the relative quantities of ore and gross values represented by the three divisions. Whether one, two or three divisions are considered the procedure is essentially the same for each. An average sample is taken from each zone. This is done by making a number of sample cuts and combining the material from all. The possibility of dividing the ore into "first-class" or shipping ore and second-class or "mill ore" should be considered also. Here the metallurgist has to consider the mining problem. If it is possible to separately mine the two classes or readily separate them after breaking, then samples are taken of each class. This feature may apply to all three zones. The result of the sampling will be to give in the most general case from three to nine separate samples.

Oxidized	First Class	Second Class	Unseparated
Intermediate			
Primary			

No hard and fast rule can be laid down for the size of the samples. It is well to provide ample material and, if it is suspected that many tests will have to be carried out, from 500 to 1000 lb. of each sample may be advisable. For the small-scale tests the gross samples can be quartered to 100 lb. The taking of the samples is best done under the supervision of the metallurgist, and while they are being taken he should examine the general features of the ore in place. The physical nature of the ore, the manner in which it breaks and the nature of the mineralization are important points. A series of specimens of minerals typical of the ore and lumps of the ore itself should be gathered for future study. If it is obvious that stopes will be carried partly in the wall-rock, specimens and samples of the walls should be taken.

Samples and specimens for examination should be carefully marked and protected from any possible contamination.

Assays and Analysis

Each sample is reduced and a sample for assay and analysis taken. An assay for gold and silver and an analysis for the more important metals are made. While in many cases a complete analysis is unnecessary, I am very much in favor of making it. It will at least serve to check the possibility of the presence of unusual or unsuspected constituents.

Mineral Determinations

The lump-ore specimens are next examined and the minerals determined. Each mineral is separated and tested. Distinction is, of course, made between valuable and gangue minerals. The unusual minerals present are determined from the collection made at the time of sampling. Where it is possible to separate clean mineral fragments the specific gravity of the constituent minerals is determined. The percentage mineralogical composition is then figured.

Physical Examination

The specific gravity of the ore in the different samples is determined. This is not as easy as it appears. If the ore is compact, determinations upon lumps are sufficiently accurate. Several pieces should be tested and the average specific gravity calculated. If the ore is porous probably the best method is to determine the

approximate specific gravity by taking large pieces and determining their volume by sand displacement. The specific gravity is also calculated from the percentage mineralogical composition. The pore space of a given ore can be determined from the calculated and determined specific gravities. The hardness of the individual minerals and the approximate hardness of the ore should be tested and determined. Any definite structure such as banding, brecciation and planes of weakness should be noted. Plasticity or toughness or other pronounced physical characteristic should also be noted. For the physical examination the lump specimens are preferable to the test samples.

Mineral Association

The general nature of the mineralization of the ore will have been determined from studies made in the mine. The detailed study is made upon the type specimens previously collected. Ores from the standpoint of mineralization may be divided into massive, banded, laminated, disseminated, fracture-plane, and irregular. The terms are in common use and no definitions are necessary. Where only one mineral is associated with the gangue the size of the individual grains and aggregations of grains and crystals should be determined. In most ores the valuable mineral aggregates vary greatly in size, and it may be very difficult to determine the average size. In this case the extremes and the relative importance of each should be determined. For example, the aggregates may be for the most part of large size, say walnut size, or they may all be small, say of the size of wheat grains. Where relative terms are used for the description of sizes they should be defined within certain limits.

Aggregates may consist of two or more crystals. Note the number of crystals, the tenacity with which they adhere to one another in the individual aggregates, the shape of the aggregate, whether it be irregular, cubical, lenticular, sheet-like or tabular and the prevalence of the form habit. In addition, where two or more heavy minerals are associated, either as individual crystals or aggregates of crystals, note the nature of the association, the relative size and shape of the individual grains, and whether one mineral is included within the crystals of the other or they come together like the parts of a mosaic.

Where minerals are coarsely crystallized and the color and luster of the individual minerals sufficiently marked to admit of ready recognition, the examination of the lump ore or the broken pieces of the sample can be effected by use of a hand magnifying glass or by simple inspection. In the case of most copper, lead, zinc and some silver ores, the simple methods mentioned suffice. When the minerals are finely crystallized, intimately associated or differentiated with difficulty, then the method of examining a polished surface of the ore with the metallographic microscope is in order. A number of type pieces are selected and significant faces smoothed and polished. Individual mineral aggregates may be selected and prepared in the same way. Where differentiation is not pronounced reagents can be used to bring out differences in texture and color by etching. Thin sections of the ore are also prepared and examined with the petrographic microscope. In the case of a very complex ore the three methods enumerated above may be necessary, but it is surprising how much can be accomplished by the simple method of examining a number of broken fragments by the first method.

Crushing and Panning

Certain ores do not give satisfactory results by the above methods. Gold ores and many silver ores fall into this division. The relatively small quantity of the gold

and the smallness of the individual particles usually prevent its recognition. Where several sulphide minerals are present the ore may be coarsely crushed and separated by a needle into its constituent minerals. By weighing and assaying each portion the presence and proportion of gold in each can be determined. In the case of fracture-plane mineralization the mineral on the fracture planes can be scraped off and assayed and the association of gold with it determined. The heavy sulphide minerals in a gold ore are usually in a finely divided condition and it is not feasible to separate by picking. The simplest method is to crush a given portion through a 20, 30 or 40-mesh screen and then concentrate it in water by means of a pan or batea.

The products obtained are concentrate, sand and slime. The concentrate should be examined for the presence of "free gold." With a microscope the size, shape and nature of the gold particles can be observed. In some cases the gold particles can be seen projecting out of particles of sulphides or attached to pieces of gangue. By weighing the products and assaying, the proportion of gold in each can be determined. By amalgamating the gold in the concentrates the proportion of free or liberated gold can be determined. By comparing the results obtained from similar tests on more finely crushed portions it is possible to determine the proportion of gold which is free, the proportion which is intimately associated with the sulphides, the proportion which is intimately associated with the gangue particles and the proportion which is in an extremely finely divided condition and associated with the slime.

With silver ores a similar series of tests can be made and the distribution of silver minerals determined. In the case of sulphide silver ores amalgamation is not satisfactory. With oxidized silver ores the concentration test is apt to be unsatisfactory. With cinnabar ores and ores where the valuable mineral is in very small bulk and finely divided the concentration test can be applied if the difference between the specific gravities of the gangue and valuable mineral is marked. The test has the somewhat objectionable feature that different results are obtained with the same material where it has been crushed to different sizes. This is due to the fact that the valuable mineral is liberated to a different degree with each crushing. The proportion of valuable mineral slimes is increased also with increased fineness of crushing. By running parallel tests on three portions, each crushed to a different degree of fineness, results of sufficient value can be determined.

The products of each test should be examined with the microscope. The concentrate will show whether the silver or other valuable mineral has been separated in part from the other heavy mineral or not. The sand portions will show whether mineral is conspicuously locked up in the gangue grains. The microscopic examination of the slime portion usually is not satisfactory on account of the difficulty of differentiation. The microscopic examination is qualitative only; the assay of the portions gives the quantitative results. Mineral associations are determined directly from the microscopic examination, and indirectly from the comparison of parallel tests on different portions, in each of which the degree of liberation of the mineral particles is different.

Use of Solvents

Solvents can in some instances be applied advantageously to the examination of gold and silver ores. The solvents are solutions of potassium cyanide, nitric acid, nitrohydrochloric acid and hyposulphite of soda. The results which can be obtained by their use will be better understood by considering examples. Crush a

portion of the sample to a 40-mesh screen size. Thoroughly agitate it for from twelve to twenty-four hours with a strong cyanide solution, say, 2 per cent. Then throw the mixture on a filter and wash the residues thoroughly. Dry and assay the residue. The difference in assay values will represent the amount of soluble gold which has been liberated in crushing. Gold tellurides are not soluble in cyanide solutions, and if these be present a different procedure is advisable. The residue obtained after the use of the cyanide solution is transferred to a roasting dish and cautiously roasted in the muffle. It is then treated a second time with a cyanide solution and after washing is assayed. By determining the gold in the cyanide solutions the result of the test is: Weight of gold in final residue or unliberated gold; weight of gold liberated by roasting; weight of gold soluble in cyanide solution and liberated by crushing. By repeating the test on portions crushed to different sizes the relation between the degree of crushing and the degree of liberation of the gold can be determined.

If a silver ore is to be tested, in which the silver minerals present are cerargyrite and argentite the procedure is as follows: Agitate a known weight of the ore which has been crushed to a 40-mesh size with a 1 to 4 solution of sodium hyposulphite for twenty-four hours. Throw on a filter and thoroughly wash. Digest the residue with nitric acid, using the concentrated acid and boiling for at least an hour. Dilute, filter and wash and assay the residue for silver. The silver in the nitric acid solution can be precipitated by sodium chloride, filtered out and determined by fire assay or wet methods. The results obtained are: Weight and proportion of silver present as silver chloride; weight and proportion of silver present as silver sulphide; weight and proportion of silver not liberated.

Solubility tests are of value in indirectly determining the nature of the valuable compounds present where they cannot readily be identified by direct methods. Obviously they are more or less limited in their application and obviously the results are sometimes open to question.

Use of Heavy Solutions

This method of separating associated minerals is unfortunately of very limited application for ore examination. Most ore minerals have a high specific gravity, and while it is possible to separate the greater number of gangue minerals from the ore minerals, the separation of one ore mineral from another is the principal difficulty. The solutions which can be used are: Solution of potassium and mercuric iodides which gives a maximum specific gravity of 3.19. A solution of thallium mercurio-nitrate which gives a maximum specific gravity of 5.3 at 76 deg. C. A solution of zinc chloride which gives a maximum specific gravity of about 2.

The first solution could be used to separate heavy from light minerals or a light from a heavy gangue mineral. The second solution would apply to a large number of miscellaneous minerals, but the heavy minerals of gold, silver and copper, zinc and lead would not admit of separation. The third solution is used for separating dirt, pyrite, rock, etc., from coal. The use of heavy solutions is a last resort. If the direct methods of observation and chemical analysis and the indirect methods of determining solubilities fail to give satisfactory results, then try the heavy solution.

Conclusion

If the physical and chemical nature of an ore is understood, and if the nature and association of the minerals constituting the ore are known, then the method or methods of treatment can be decided upon. The limitations of ore-dressing, solution and smelting

methods from the economic, mechanical, physical and chemical standpoints are fairly well established. The mechanical appliances for drying, crushing, sizing, classification, concentration, sorting, washing, dewatering, filtration, magnetic separation, etc., have reached a high state of development. Mechanical appliances for conveying, elevating and excavating are available. Many examples of the arrangements of mills and reduction plants are to be found in technical publications. The metallurgist thus marshals three lines of thought, the ore, the fundamental steps in the treatment, and the mechanical appliances necessary to carry these out.

While a detailed study of the ore is essential it is not necessary in every case to carry out the general method described. The experienced metallurgist will know where the line can be drawn and can save himself unnecessary work. In addition certain tests are applied without, or with very limited, preliminary ore studies, and if favorable results are obtained the information may be sufficient to decide upon a method of treatment. Confirmatory tests are also carried out. These are first performed upon a small scale, and then the most successful repeated upon as large a scale as the available apparatus permits. Mill runs are often used for the determination of the details necessary for the design of the ore-treatment plant. They serve the additional purpose of confirming the studies and deductions of the metallurgist.

Golden, Colo.

The Ostwald Process of Oxidizing Ammonia to Nitric Acid

BY FRED C. ZEISBERG

Within the past year a great deal of interest has been shown in the "nitrogen problem" and considerable agitation has been rife with respect to making the United States independent of foreign supplies of nitrates in the event of war. One phase of this nitrogen problem is the catalytic oxidation of ammonia. The following article collects practically everything which has appeared in the literature concerning this process. It does not claim to present anything new, but simply aims to bring into a condensed and rational form the various references which have appeared from time to time.

The process of oxidizing ammonia to nitric acid is commonly known as the Ostwald process, not because this process was invented by Wilhelm Ostwald, but because the problem of the catalytic oxidation of ammonia was first attacked by him in a scientific manner and solved so successfully that this reaction could be used on the commercial scale. In the following pages all processes of oxidizing ammonia catalytically, and there are several of them, will be treated under the general head of the "Ostwald Process."

As early as 1839 Kuhlman¹ found that ammonia could be oxidized to nitric acid in the presence of catalytic agents. He mentions Cu, Fe, Ni, Pt and even Cu(OH)₂. Motay² mentions the use of lead manganate and permanganate, sodium manganate and lead chromate. In 1891 Warren obtained ammonium nitrite when ammonia and oxygen were passed over platinized asbestos at a dull red heat. Marston, in 1900, secured nitric compounds by passing the gaseous mixture over hot copper and other similar contact bodies.

That ammonia could be oxidized with ease was then well understood when Ostwald took up the study of the reaction in 1900. He discovered the conditions under which the reaction proceeded, and on the laboratory scale could easily obtain a yield, as HNO₃, on the NH₃,

¹Annalen der Chemie, 1839, 29, 281.

²Berichte der Deutschen Chemischen Gesellschaft, 1871, 4, 891.

taken, of over 85 per cent. Platinized platinum, *i.e.*, smooth platinum roughened by depositing upon it a thin layer of platinum sponge, was found the best catalyst, platinum black or sponge alone proving far too active. It was also found that only a thin layer of the catalyst worked best and that the gas mixture must be passed over the catalyst at a high velocity. A thick layer of catalyst or a low gas velocity caused the HNO_3 already formed to break down further into elementary nitrogen and water.

Having perfected the mechanical details of his process, Professor Ostwald, in 1902, applied for patents in the principal countries of Europe and in the United States. Because of prior publication of the essential features as scientific facts no patent was allowed in Germany. French Patent No. 317,544, English Patent No. 698 of 1902, Swiss Patent No. 25,881 and U. S. Patent No. 858,904, dated July 2, 1907, were allowed, however. The latter patent mentions the use, as catalysts, of palladium, iridium, rhodium, the oxides, especially the higher ones of manganese, lead, silver, copper, chromium, nickel, cobalt, vanadium and molybdenum; though platinum is best. The contact mass is heated to 300 deg. C., and the heat of the reaction then maintains it at the proper temperature. It is necessary to pass the gas at such a rate that a slight increase in rate would result in the appearance of unconverted ammonia in the exit gases, otherwise the yield will suffer. One of the claims also mentions a heat exchanger, whereby the heat of the exit gas is given up to the entering gases.

In 1909 a factory was built at Gerthe, near Bochum, Westphalia, with an annual production of 2400 tons of 53 per cent nitric acid. According to Norton¹ the operation of this factory has been very successful. A private communication states that from January, 1911 to August, 1912, this plant obtained an efficiency of 89.6 per cent on a monthly production of 130 tons of ammonium nitrate. The efficiency of conversion was 83 per cent and the efficiency of the absorption was 97 per cent. This plant operates on coal-tar ammonia, which is interesting in view of statements recently made in the literature that nothing but ammonia made from cyanamid was suitable in an oxidation process. Commercially, this factory is understood to have been a success.

According to another article² the above factory makes 2000 tons of ammonium nitrate per annum. This product has never appeared on the market, so it is presumably taken by the German government. In 1912 and in 1913 this company paid 8 per cent dividends to its stockholders.³

In 1910 the process was purchased by the Nitrates Products Co., Ltd., London, who took over the Gerthe plant. This company was promoted⁴ by Mr. A. S. Barton and reorganized under the name of the Nitrogen Products & Carbide Co. and is capitalized⁵ at £2,000,000. A new plant was erected at Vilvorde, Belgium, which produced 40 to 50 per cent nitric acid, higher strengths being produced by concentrating with sulphuric acid. Nitrates, Ltd., built cyanamid works at Alby, Sweden, and Notodden, Norway. In addition it expects to develop 400,000 horsepower in Iceland at the Ditterfoss, and three additional water power sites in Norway to produce a total of 600,000 horsepower. Recent articles⁶ indicate that the present name of this company is the Nitrogen Products & Carbide Company, and that their finances have been considerably mismanaged,

so that it has been necessary to assess the stockholders. No nitric acid is being made by them at the present time, their only factory, at Vilvorde, Belgium, being in the hands of the Germans.

A more recent article⁷ states that the experience of countries other than Germany and Belgium has been very unfavorable as regards the Ostwald process, and that it is doubtful whether a single Ostwald plant is now in use outside of Germany.

The fact that no patent protection exists in Germany results in the greatest secrecy being observed in connection with the details of the process, and it is practically impossible to find statements of much value in the literature. This is especially true since the outbreak of the European war, no articles of any authoritative nature having been published recently.

The original converters were so constructed that an exchange of heat occurred between the incoming gas and the outgoing gas. This served not only to keep the catalyst at the proper temperature of 300 deg. C., because of the strongly exothermic character of the reaction $\text{NH}_3 + 2\text{O}_2 = \text{HNO}_3 + \text{H}_2\text{O}$, in which ninety-seven calories are evolved⁸, but also served to regulate this temperature, even with considerable variations in the rate of gas flow. The thickness of the catalyst layer and the gas velocity are so chosen that the time of contact between the two does not exceed one one-hundredth of a second.⁹

The proportions between the NH_3 and the air can be varied considerably. If an excess of NH_3 is used ammonium nitrate is the end product. If the NH_3 and air are so proportioned that the relation is that shown in the equation $\text{NH}_3 + 2\text{O}_2 = \text{HNO}_3 + \text{H}_2\text{O}$, and no water is dripped on the absorption towers, the maximum strength of nitric acid theoretically obtainable is 77.8 per cent. Ostwald himself¹⁰ states that no less air should be used than represented by the equation $2\text{NH}_3 + 7\text{O} = 2\text{NO} + 3\text{H}_2\text{O}$. In this case passing the gases very rapidly would result in obtaining a mixture of ammonium nitrate and ammonium nitrite in the exit gases.

According to Camille Matignon¹¹ the above equations do not represent the reaction correctly, as at the temperature of the reaction neither NO , nor HNO , can exist. The equation should hence be written $2\text{NH}_3 + 5\text{O} = 2\text{NO} + 3\text{H}_2\text{O}$. Of course, if an excess of air is used the NO would readily be oxidized to NO_2 , as soon as the temperature is sufficiently reduced. This process of oxidation begins as soon as the temperature drops below 600 deg. C., but cannot become complete until the temperature drops to 140 deg. C.¹² At this lower temperature, moreover, the reaction velocity is very low, so that an appreciable time must elapse until the reaction becomes complete.

Apparently the only diagram of a converter ever published is one recently appearing¹³ in an abstract of an article by G. Schüpphaus in *Metal und Erz*, 1916, Vol. XIII, 21. In this converter the catalyst is a platinum gauze, electrically heated to 700 deg. C. The gases enter below and pass upward through the gauze, no heat exchange being effected. At this temperature the conversion is almost quantitative, steam and nitric acid (HNO_3) being the end products, which would indicate that the reaction equation is $4\text{NH}_3 + 5\text{O}_2 = 4\text{NO} + 6\text{H}_2\text{O}$.

To keep the gauze heated, electricity is supplied at 25 volts and 135 amp., *viz.*, 3.375 kw. No definite state-

ment is made as to the capacity of a converter, but judging from a description, included in the article, of an ammonia gas purifying apparatus connected with the factory, three converters handle from 125 to 1250 kg. of NH_3 per day. Hence one converter can probably handle about 240 kg. per day or 10 kg. per hour. Since at 85 per cent conversion, 10 kg. of NH_3 will make 31.5 kg. of HNO_3 , 100 kg. of HNO_3 will require about 10.75 kw.-hr. to keep the catalyzer hot.

The amount of platinum necessary to effect the conversion is about 47 grams per 100 kg. of HNO_3 per twenty-four hours.¹⁰ The platinum loss due to wear and tear is about 3 per cent per month, and the elements have to be completely renewed once a month. Since fairly high prices can be obtained for platinum scrap the cost of renewal is the cost of supplying the platinum due to loss and the cost of exchanging the scrap platinum for new platinum.

It has not been found possible to ascertain the dimensions of a converter, but what information is available would point to the use of only small converting units, containing perhaps not more than 50 grams platinum per unit. The converters are built of iron up to the contact element, and beyond this of iron lined with aluminium. According to a patent¹¹ to Ostwald (German No. 207,154) nickel steel is not attacked by hot, nitrous gases and it can hence be used in place of aluminium-lined iron. At a point far enough away from the converter for condensation to occur, the gas lines must be made of an acid-resisting material, such as chemical-ware.

Since this process is a catalytic one, it suffers from the disadvantages of all catalytic processes, namely, the contact substance is "poisoned" by certain substances, which must be very carefully removed from the entrance gas by a suitable purification treatment. It is presumably for this reason that statements have appeared to the effect that only ammonia from cyanamid is suitable for this process, and that ammonia from coal tar, even when carefully purified, is likely to cause trouble by poisoning. An interesting bit of information from the other side is that the Oesterreichische Verein für Chemische und Metallurgische Production¹² has patented (German Patent 276,720), a process of purifying ammonia from cyanamid with caustic alkali and earth alkali solutions. When this was not done it was found that despite a careful filtration of the gas, to remove dust, the platinum contact elements became brittle and covered with a coating of silicic acid, after being in use only a short time. This was due to the presence in the gas of silicon, phosphine and acetylene.

To show that considerable work has been done on the oxidation of ammonia by investigators other than Ostwald, there are shown below several patents. Thus Frank and Caro (German Patent No. 224,329), propose the use of thorium oxid, or thorium oxid in combination with the oxids of other rare metals.

Fr. Baeyer & Co. of Elberfeld (German Patent No. 168,272), use cupric oxid, ferric oxid, etc. A current of air containing 4 to 5 per cent NH_3 is passed over the catalyzer heated to 600-750 deg. C. Above 650 deg. the NH_3 is converted into N_2O exclusively.

Jones, Morton & Terzief (U. S. Patent No. 1,037,261) use the plumbates of magnesium, zinc, aluminium or cadmium, heated to 700-750 deg. C. The conversion to N_2O is practically complete and the heat of reaction is sufficient to maintain the catalyzer temperature with but little pre-heating of the gases.

Rohmer (U. S. Patent No. 1,096,392, assigned to Farbwerke vormals Meister, Lucius und Brüning),

patents the addition of only sufficient air to NH_3 , so that the hydrogen of the ammonia removes all the oxygen of the air. The exit gases contain then only nitrogen, steam and oxids of nitrogen. By removing the two latter by condensation, pure nitrogen, available for the manufacture of ammonia by synthesis, is left. This corresponds to French Patent No. 453,845.

Schick (U. S. Patent No. 971,149, assigned to Chemische Fabrik Griesheim Elektron) patents the manufacture of a catalyzer suitable for causing the oxidation of ammonia. Tile is dipped in a platinum chlorid solution, dried and heated, causing the deposition of platinum black. The tile is then baked, causing the platinum to collect in minute globules. This catalyzer is claimed to retain its efficacy much longer than the platinized platinum recommended by Ostwald.

The above list does not claim to be complete. It is inserted simply to show that there are many investigators working on this particular problem. It is probable that of the processes mentioned above, the one of Frank and Caro has been developed to the greatest extent. Thus, Frank S. Washburn¹³, president of the American Cyanamid Company, states that there has recently been developed a new process for the oxidation of ammonia, which does away with the limitations of the Ostwald process. The units can be made large or small and their cost is rather low.¹⁴

It is reported¹⁵ that the Frank and Caro process of oxidizing ammonia has been developed in Germany to the extent of producing nitric acid at the rate of 120,000 tons per annum. The guaranteed efficiencies of two of the processes are from 90-95 per cent. An English company (Nitrates, Ltd.), is establishing cyanamid nitric acid factories throughout the allied countries of Europe and guaranteeing an efficiency of 90 per cent. It thus appears that commercially the oxidation of ammonia has proved successful and that it may be considered to be a well-established industry.

Regarding the cost of the process, only one detailed estimate of cost has been encountered in the literature. This is an abstract¹⁶ from the Iron and Coal Trades Review (London) of May 23, 1913, containing a complete estimate of the cost of a small English factory for making nitric acid out of ammonia liquor.

Below is given a revision of this estimate based on American conditions, and considered only from the standpoint of conversion cost, i.e., it is assumed that a supply of pure ammonia gas is already available.

In this estimate it is assumed that there are thirty converters in one building and that in a separate building is the absorption and condensing apparatus, consisting of five absorption towers 60 ft. high. Three coolers and one storage tank are used in supplying acid to each tower. The necessary pans, monteius, compressors, etc., are all included. It is further assumed that each converter unit produces 200 kg. of 36 deg. (53 per cent) nitric acid per day and that the total output per month is 148.4 tons of 53 per cent nitric acid = 78.7 tons HNO_3 = 173,500 lb. HNO_3 .

Plant for conversion (converters).....	\$5,000
Condensing and absorption plant.....	17,500
Foundations for towers and iron work.....	5,000
Acid storage tanks.....	750
Air compressor and motor.....	3,000
Platinum ¹⁷ 1500 g. at \$1.67.....	2,500
Buildings and foundations.....	10,000
Unforeseen outlays.....	3,750
Total.....	\$47,500

The running expenses are:

Power.—For lifting the liquid in the absorber house

¹²Metallurgical and Chemical Engineering, 1916, XIV, 418.

¹³Scientific American Supplement, Sept. 13, 1913, 162.

¹⁴This is equivalent to \$51.80 per troy ounce.

¹⁵Die Chemiker Zeitung, 1915, 848.

¹⁶Scientific American Supplement, Sept. 13, 1913, 162.

¹⁷Journal of the Society of Chemical Industry, 1909, XXVIII, 365.

¹⁸Die Chemiker Zeitung, 1915, 848.

and for direct air pressure, 12 to 15 horsepower, and for running a fan 5 additional horsepower, say 20 horsepower altogether. This means 14,400 horsepower hours per month (30 days) and at 2.5c. per horsepower-hour, the power would cost \$360.

Platinum.—For the whole plant thirty contact elements, weighing 50 grams each are required. The total wear and tear may be estimated at 1.5 grams per day or 45 grams per month. The contact elements can be used a month or six weeks, after which they must be scrapped as old metal and replaced with new. This exchange can be made for about 6 cents per gram. Assuming an exchange once per month, the cost of exchanging the 1455 grams would be \$87.30, and the cost of replacing the 45 grams lost would be \$75.00, a total monthly expenditure for platinum of \$162.30.

Wages.—For superintending and operating valves two men are sufficient per shift; for cleaning, a third man is required (original article). In larger installations it is assumed that these three men could care for twice as much apparatus. Assuming the foreman would get 45 cents, his helper 35 cents, and the cleaner 30 cents per hour, the labor cost would be \$396.00 per month on the three-shift basis. A superintendent at \$150 per month could easily look after a plant four times the size.

The monthly expenditures would then be:

Power	\$360.00
Platinum	162.30
Wages	396.00
Repairs	125.00
Superintendence	37.50
Interest and depreciation at 15 per cent per annum	594.50
	\$1,675.30

This makes the cost of conversion 0.965 cent per pound HNO.

The original investment cost per metric ton of HNO per year is hence \$50.30 for the converting and absorption apparatus and the conversion cost, including interest and depreciation as shown above, is \$21.30 per metric ton. In applying the above figure the cost of the ammonia necessary to make a ton of HNO, would have to be added to the conversion cost. Thus, with ammonia at 7.5 cents per pound the cost of HNO, per metric ton would be, on the basis of an 85 per cent conversion, \$52.50 for NH₃ + \$21.30 for conversion or a total of \$73.80 per metric ton of HNO,. It should be remembered that this is for HNO₃ in the form of 36 deg. Baume or 53 per cent nitric acid.

To see how the above costs compare with the costs obtained by other estimators or with other processes, it might be mentioned that an original investment cost of \$50.20 and a conversion cost of \$23.50 per metric ton of nitric acid per annum were assumed by O. Diefenbach.²⁴ In his estimate he assumed 10 per cent interest on the capital investment. This same calculation gives the cost of concentrating HNO, from 53 per cent to 93 per cent as \$12.43 per metric ton of HNO or 0.563 cent per pound HNO₃.

From another source²⁵ the original investment cost is \$51.90 and the conversion cost is \$28.10 per short ton, which is equivalent to \$57.20 for the original investment and \$31.00 for the conversion cost per metric ton of HNO, as 53 per cent acid. The above estimate and the one in the preceding paragraph, as well as the detailed estimate on page 13, are for small plants. For large plants the article in the *Chemical Trade Journal* gives an original investment cost of \$53.30 per short ton and a conversion cost of \$35.65 per short ton, which is equivalent to \$58.80 for the investment cost and \$39.30 for the conversion cost per metric ton of HNO₃,

as concentrated acid. Some additional figures given in this same article would indicate that the investment cost, when making 53 per cent HNO₃ in large plants, would be \$37.40 and the conversion cost \$21.20 per metric ton of HNO₃. This would give a concentrating cost of \$14.45 per metric ton of HNO₃ or 0.656 cent per pound HNO₃.

Washburn states²⁶ that "roughly speaking and with power at \$10.00 per horsepower year there is to the credit of ammonia from cyanamid about half the cost of weak nitric acid made by the arc process, available for oxidizing the ammonia to nitric acid. The indications are that the cost will not amount to more than half this difference." With power at \$10.00 per horsepower year, a metric ton of HNO₃ made by the arc process and in the form of 53 per cent acid would cost about \$50.00, which, according to the above statement, would make the conversion cost from \$12.00 to \$15.00 per metric ton of HNO₃. This estimate should be regarded conservatively, however, as it is based only on general statements.

Summarizing the above estimates, we obtain the following table in which the figures under (a) refer to small plants and those under (b) to large plants:

Per Metric Ton of 2205 Lbs. of 100 Per Cent HNO ₃	Scientific Amer. Suppl.	Diefenbach	Chem. Trade Journal	Washburn
Investment cost	\$50.30	\$50.20	(a) \$57.20 (b) \$37.40	
Conversion cost to 53 per cent acid	21.30	23.50	(a) 21.20 (b) 14.45	\$12-\$15
Concentrating cost to 93 per cent acid		12.43	(a) 14.45 (b) 39.30	
Conversion cost to 93 per cent acid per lb. 100 per cent HNO ₃		35.93	(b) 39.30	
		1.632c. (b)	1.583c.	

There is a fair amount of agreement among the first three estimates, but the estimate of Washburn is so much lower that it should be regarded with reserve, especially when it is considered that it is only a general statement upon which the estimate is based. On the other hand, it must be remembered that this process has made immense advances in Germany very recently, and as Washburn's statement was made at least a year later than the appearance of the other estimates, it is quite likely that this process can be carried out more cheaply than the older estimates would indicate.

The true figure probably lies somewhere between the two, i.e., the conversion cost is probably about \$18 per metric ton of HNO₃ in the form of 53 per cent acid, or 0.816 cent per pound HNO₃. To this must be added the cost of the ammonia and the cost of concentrating the acid to 93 per cent. Even with ammonia at 5 cents per pound and a conversion of 85 per cent, the ammonia would cost 1.587 cent per pound HNO₃, and the concentrating cost would hardly be less than 0.375 cent; so that HNO₃ in the form of 93 per cent acid, could hardly cost less than 2.778 cents per pound by the Ostwald process.

The question of the profitability of the Ostwald process, on the basis of the above figures, depends on several considerations. The price of ammonia is governed by the price of sodium nitrate, the prices of these two substances always being approximately equal when calculated to a basis of their nitrogen content. If it costs less to convert ammonia to nitric acid than it does to convert soda to nitric acid, it will naturally be more profitable to use the Ostwald process than the present process. In this conversion the cost of sulphuric acid must be included in the latter process. But, consideration must also be given the fact that the yields with the two processes are different, that with the Ost-

²⁴Transactions American Electrochemical Society, 1915, XXVII, 385.

²⁵This becomes \$58.80 when the concentrating apparatus is included.

²⁶Chemische Industrie, 1914, 265.

²⁷Chemical Trade Journal and Chemical Engineer, 1914, 283.

wald being usually taken as 85 per cent, that with the present process at 97 per cent. Therefore, in order to break even and with equal cost of nitrogen in the raw products, the Ostwald process must be capable of converting its raw product into nitric acid more cheaply than the present process in order to take care of the greater amount of nitrogen lost in the conversion, and the difference in conversion costs must hence be greater the higher the initial cost of the nitrogen.

The cost of conversion by the Ostwald process, 93 per cent nitric acid being the end product, we have seen could hardly be less than 1.191 cent per pound HNO_3 . The cost of nitric acid made from nitrate of soda is probably at least 1.75 cents per pound for labor, repairs, etc., and sulphuric acid. The cost for nitrogen, with nitrate of soda at 2.64 cents per pound, would be 3.750 cents for the retort method and $97 \div 85$ of this or 4.280 cents for the Ostwald process per pound HNO_3 . These figures are arrived at by assuming that 1.42 lb. of nitrate of soda are used per pound 100 per cent HNO_3 , which is about the case with a yield of 97 per cent; $1.42 \times 2.64 = 3.75$ and $97 \div 85$ of $3.75 = 4.28$ cents. If nitrate of soda should fall to 1.5 cent per pound, below which it is hardly conceivable it could ever go, the nitrogen cost per pound HNO_3 would be $1.42 \times 1.5 = 2.13$ cents for the retort process and $97 \div 85 \times 2.13 = 2.43$ cents for the Ostwald process.

We would then have:

	Ostwald	Retort
Nitrate of soda at 2.64c., NH_3 at 13 $\frac{3}{4}$ c.		
Cost of conversion.....	1.191	1.750
Nitrogen cost.....	4.280	3.750
Total cost.....	5.471	5.500
Nitrate of soda at 1.5c., NH_3 at 7.5c.		
Cost of conversion.....	1.191	1.750
Nitrogen cost.....	2.430	2.130
Total cost.....	3.621	3.880

From these figures it can be seen that with the present price of nitrate of soda the Ostwald process can make nitric acid for only a fraction of a per cent less than the retort process. If the price of nitrate of soda decreases, however, and with it the price of ammonia, the Ostwald process becomes increasingly more profitable. With nitrate of soda at 1.5 cent per pound the cost of the Ostwald process for making nitric acid would be 93 per cent of the cost of making it by the retort process.

It is a little difficult, at first, to see why the Ostwald process should not be profitable now, using by-product ammonia, which can certainly be produced for less than 13 $\frac{3}{4}$ cents, the ammonia price corresponding to a nitrate of soda price of 2.64 cents per pound. A little consideration will show, however, that it is much more to the producer's advantage to sell his by-product ammonia for 13 $\frac{3}{4}$ cents than to convert it into nitric acid to be sold at only a very slight advance over this price.

It is also a little difficult to see why the Ostwald process should be increasingly more profitable as the nitrate of soda price falls. The reason is that as the nitrate of soda price falls the ammonia price falls correspondingly. The conversion cost remains the same with both processes, however, being approximately a half cent per pound of HNO_3 higher with the retort process. At the present price of nitrate of soda this difference is neutralized by the larger amount of raw material needed by the Ostwald process on account of its lower conversion yield. As the cost of the raw material falls, however, the raw material makes up an increasingly smaller proportion of the total cost, so that the higher conversion cost of the retort process begins to influence more and more the total cost.

The figures obtained in the foregoing estimate do

not agree very well with the statement of Washburn* that the cost of making nitric acid from ammonia in Europe at the present time is about 70 per cent of the cost of making it from soda, even though his statement is based on a 90 per cent conversion for the contact process. Of course, it is unknown whether the above statement refers to normal conditions in Europe, or the present abnormal ones.

Regarding the advantages and disadvantages of the Ostwald process, they seem to sum up as follows:

Advantages.—The process is continuous, which makes for a maximum return from the investment. It is capable of installation in small units, which makes for flexibility in operation. The exit gases from the converters are several times as concentrated as those from any arc furnace, which allows of enormously cutting down the size of the absorption apparatus. The raw product, ammonia, is easily obtainable in the United States, making us independent of foreign supplies in case of war. The power costs are very low, hence the plant could be located almost anywhere.

Disadvantages.—It is only a step and not a complete process, hence the plant would have to be located with respect to economy of freight on incoming supplies, either cyanamid or ammonia liquor. It is hardly profitable unless the cost of ammonia drops to a figure that is improbably low.

Conclusion.—So far as information is available it would hence appear that the Ostwald process, and this term is meant to include all processes of the catalytic oxidation of ammonia, is hardly in a position to compete with even the present process of manufacturing nitric acid from nitrate of soda. Even with a considerable reduction in the price of ammonia the possible profit is so small and the reliability of the figures on which the cost estimates are based is so problematical that it would seem a rather doubtful proposition to entertain.

It should be remembered that the foregoing reasoning is based on a yield of only 85 per cent for the Ostwald process. If it could be possible, for example, to raise the yield to 97 per cent, the yield usually obtained by the retort process, the Ostwald process could produce nitric acid for about a half cent per pound less than the retort process. There is no general information available at present, however, which would indicate that the conversion efficiency of the Ostwald process is much in excess of the 85 per cent used throughout this paper.

When it comes to comparing the cost of nitric acid made by the Ostwald process with the cost of nitric acid made by the arc process, relatively accurate figures for which are available in the literature, the cost by the Ostwald process is seen to be so high that there is little use giving it further consideration.

It should be emphasized again, however, that due to the secrecy observed in the country where the process was evolved, with respect to making public the details of the process, the information obtained from the literature cannot be credited to too great an extent. This information is the best we have at hand, however, at the present time. After the cessation of hostilities in Europe it may come to light that the Germans have perfected and cheapened this process to such an extent that it might prove worth considering, for installation in small units at isolated points. It seems very unlikely, however, that it can ever be cheapened to an extent where it can compete on the large scale with nitric acid by the arc process, unless a much better yield of ammonia can be obtained than seems to be the case at the present time. Ammonia will always be too valuable *per se*, to consider making cyanamid, how-

*Metallurgical & Chemical Engineering, 1916, XIV, 138.

ever cheaply, for the sole purpose of converting it to nitric acid.

There is appended a bibliography which collects the references given throughout the text, and in addition gives several other references which were not directly referred to. Some of these are only short notices, others long articles giving much detailed and general information, but all have a bearing on the process under consideration. This list is not by any means complete, but the compiler believes that no important reference in any of the more well-known journals has been overlooked.

ADDENDUM

Since the above article was written two patents have appeared (U. S. 1,193,796 and 1,193,797) which might be construed to alter somewhat the reasoning expressed in the conclusions. These patents deal with the oxidation of ammonia and claim to obtain a 95 per cent conversion. Their novelty lies in the cooling of the ammonia-air mixture up until the very time it comes in contact with the hot catalyser, in distinction to the principle of heat exchange mentioned in Ostwald's original U. S. patent. Because no heat is carried to the catalyser by the gases it must be heated in some other manner, preferably electrically.

As the claim that a 95 per cent conversion can be obtained appears only in a patent specification and has not yet been substantiated, so far as any information available in the literature would indicate, it would seem as yet a little too early to assume that these patents have any serious bearing on this problem. Later developments may show them to be of great importance, but time will be required to prove this.

Western Metallurgical Field

Company Reports

Inspiration Copper Company's report for the year 1915 states that copper production began in June, 1915, the first unit of the new mill going into operation on June 29. During the last six months of the year copper production amounted to 20,445,670 lb., of which 20,067,310 lb. was recovered from 778,851 tons of ore concentrated and 378,360 lb. from oxide ore shipped to smelter. The ore averaged 1.7 per cent copper, of which 0.226 per cent was in oxidized form. Tailings assayed 0.373 per cent copper, of which 0.18 per cent was oxidized. Flotation concentrates averaged 37.63 per cent copper, and table concentrates 13.12 per cent. The average assay of all concentrates made was 32.67 per cent copper, and the percentage recovery of all copper was 79.95. Average percentage

recovery of sulphide copper was 88.56. Ratio of concentration was 24.6:1. The following tabulation of costs is given for the treatment of 778,851 tons of ore, producing 20,067,310 lb. copper.

	Per Lb. Copper	Per Ton Ore
Mining	2.644c	\$0.68110
Coarse crushing	0.113	.02910
Ore hauling	0.079	.02025
Concentrating and royalty	1.389	.48675
Concentrate hauling	0.006	.00160
	4.731c	\$1.21880
Smelting, freight, refining, marketing, etc.	3.455	.76420
	8.136c	\$1.98300

The saving of sulphide mineral by flotation has improved since the mill first went into commission and has not only exceeded the expectations of a year ago, but is now better than the average for 1915. For the month of February, 1916, the saving of sulphide copper was 91.1 per cent. Coal tar continues to be used as the chief component of the flotation-oil mixture. An interesting item in connection with the test mill is that it treated 373,705 tons of ore and paid for its cost of construction, operating expense, the present average cost of mining on ore treated, and left something besides. The cost per ton of daily capacity for the equipment of the property to mine and mill 14,400 tons daily is given as \$833, of which \$625 was for equipment of mine and mill, water supply, power, mill site, tailing land, railroad, etc., and \$208 for advanced mining expenditures to prepare for an output of 14,400 tons per day. Operating costs for mining and milling at Inspiration probably will range from \$1 to \$1.15 per ton of ore.
